Master’s Thesis in Computing Science
Supervisor: Johan Jeuring

Abstract

This report describes what polytypic programming is, a new system for writing polytypic functions, and a number of useful example functions including generalised versions of map, zip and a specific lazy array based unification algorithm.

Sammanfattning

Denna rapport beskriver hur man med ett programsystem automatiskt kan generera funktioner som fungerar för alla trädtyper och detta systems tillämpning på ett antal användbara funktioner som map, zip och en speciell unifieringsalgoritm baserad på lata fält.
1 Introduction

This report describes polytypism, unification and a specific array based polytypic unification algorithm. We will also describe a system for generating code for polytypic functions.

1.1 Background

As an example of a polytypic function we can take unification. Unification is the process of making two expressions containing variables equal by substituting expressions for the variables. Unification is used for type inference by unifying type expressions containing type variables, in automatic proof systems by unifying proofs with proof methods and in compilers to unify the patterns of function definitions with function calls [10]. Each of these applications requires a unification algorithm for their specific type. As the unification algorithm is so widely used it would be nice to have a general algorithm for unification parametrised by a datatype. This means that given a datatype, it automatically generates a unification algorithm for this type. This is a typical polytypic algorithm and we will give an implementation of it in section 6.5.

Interest in polytypic functions arose when it became clear that most of the theory of lists [1] could be generalised to other datatypes [11]. This has theoretical interest as many of the powerful methods of calculating programs from specifications, and thereby proving their correctness, that had been developed for list based programs [5] also could be generalised [2].

The practical interest comes mainly from the prospects of not having to rewrite all those standard functions that are defined for lists in most functional languages for every datatype in a program. After having written a number of versions of the function map on different tree types one realises that with a suitable theory these should be possible to generate automatically. The categorial theory of datatypes [13], where datatypes are initial fixpoints of functors, provides a sound mathematical basis for defining and reasoning about polytypic functions. One actual implementation of a system for automatic generation of polytypic functions, Hollum, was written by Jeuring et. al. [7].

Hollum reads a Haskell program, parses it, extracts the datatype definitions, generates a number of polytypic functions for each of the types and outputs the result as a Haskell program. The system is self contained but does not handle all tree types as it can not generate code for mutual recursive functions, and also requires that all constructors in the types have exactly one argument (though that argument may be a tuple). The fact that this last requirement is caused by the parser used, and the difficulty in analysing and optimizing the output (which is text) made me interested in

1. Also called type parametric or generic function.
writing a system that only works from and to parsed programs as there are already
enough parsers and compilers to take care of the rest.

1.2 Preliminaries and notation
We will use the purely functional lazy programming language Haskell [4] in the
examples, but they would probably work with minor modifications in other func-
tional languages as ML or Scheme. All code in the system as well as all the code
generated by the system runs in Gofer [9], a language that includes most of Haskell
and has a fast interpreter which has been used in the development of the system.

In Haskell (and Gofer), function composition is denoted by a period and has lower
precedence than application. (Application is as usual written with juxtaposition)
This means that \((\text{fst} \ . \ \text{map} \ f \ . \ \text{sort}) \ l)\) will be interpreted as
\(\text{fst} \ (\text{map} \ f \ (\text{sort} \ l))\). Anonymous functions (often called \(\lambda\)-expressions) are
written \((\lambda \ args \to \ exp)\) so that the definition \(f \ x \ y = 1+x+y\) is equivalent to
\(f = (\lambda \ x \ y \to 1+x+y)\). Infix operators, such as + can be made prefix by wrapping
them in parenthesis; (+), and a normal function \(\text{func}\) taking at least two argu-
ment can be made infix by using single backquotes; ‘\(\text{func}\)’. Comments are written
as:\{-- comment section, possibly many lines long --\}
-- line comment, extends to the end of the line
Expressions can be explicitly typed by writing \(exp :: \text{type}\.

We will write \(\text{const} :: a \to b \to a\), where \(\text{const} \ x \ y = x\) for the constant
function. (Often written with just \(K\) but in Haskell words starting with capital letters
are type constructors.) We will use the operator \((++) :: [a] \to [a] \to [a]\) to
concatenate two lists and \(\text{concat} :: [[[a]]] \to [a]\) to concatenate a list of lists.

1.3 Overview
Section 2 introduces polytypism and gives some simple examples of polytypic
functions. Section 3 describes a number of polytypic functions that are generated by
the system in more detail. In section 4 we show program construction combinators
with which the code for polytypic functions can be built. Section 5 describes a sys-
tem for generating polytypic functions and its implementation. In section 6 we
describe unification and we generalise a specific lazy unification algorithm to a pol-
ytypic unification algorithm. We end the report in section 7 with some concluding
remarks.

In appendix A we show all the code generated by the system for two directly recur-
sive types and one pair of mutually recursive types. The prelude in appendix B con-
tains some common functions used by the functions defined in appendix A.
2 Polytypism

A polytypic program is a program that works for types of different structures. There are at least two other kinds of polymorphism in functional programming. Normal (parametric) polymorphic functions that can be written in most functional languages work for a class of types having the same structure but with different values of the type variables. An example hereof is length which calculates the length of a list, no matter what type the list elements have. Overloading, or ad-hoc-polymorphism, is yet another way of making (apparently) the same function work for a class of types, but here one definition of the function has to be supplied for every type in the class. A typical example of an often overloaded function is + which normally works both for integers and floating point numbers.

A polytypic function has one definition that works even for types of different structure. It can but need not be polymorphic in the traditional sense; the function alleven that returns true if and only if all integers in a structure are even is polytypic, but not polymorphic.

In the following two sections we will give some examples of polytypic functions.

2.1 Map

One simple example of a polytypic function is the generalisation of map. The commonly used map_L (normally called just map) on lists takes a function f and applies it to all elements (if any) in the list. The essence here, which can be generalised to other types than lists, is that map takes a function and applies it to all elements of a data structure without changing the form of the structure. In figure 1 and 2 we give the definitions of map for two simple types. Note the similarity between the type definitions and the function definitions.

| data List a = Nil | map_L :: (a -> b) -> List a -> List b |
| | map_L f Nil = Nil |
| | map_L f (Cons x xs) = Cons (f x) (map_L f xs) |

FIGURE 1. The definition of map for lists.

| data Tree a = Leaf a | map_T :: (a -> b) -> Tree a -> Tree b |
| | map_T f (Leaf x) = Leaf (f x) |
| | map_T f (Bin l r) = Bin (map_T f l) (map_T f r) |

FIGURE 2. The definition of map for simple binary trees with information in the nodes only.

2.2 Cata

A more general and very powerful polytypic function is cata\(^1\). On lists cata_L is normally called foldr (fold right) and takes a start value, an operator and a list and

\(^1\) cata abbreviates catamorphism
inserts the operator between the elements of the list, with the start value on the far right end. (See figure 3)

| data List a = | cata_L :: b -> (a -> b -> b) -> List a -> b  
| Nil             | cata_L e op Nil       = e  
| Cons a (List a) | cata_L e op (Cons x xs) = x `op` (cata_L e op xs) |

FIGURE 3.  
The definition of cata for lists

Some simple examples of functions defined by list-catamorphisms are:

sum_L :: List Int -> Int
sum_L   = cata_L 0 (+)
all_L :: (a -> Bool) -> List a -> Bool
all_L p = cata_L True (\x b -> (p x) && b)

where sum_L computes the sum of a list of numbers and all_L p determines if all elements of a list satisfy the predicate p.

The key to generalising the definition of cata to other tree types is to observe that cata_L simply replaces the datatype constructor \texttt{Nil} with the supplied constant \texttt{e} and the constructor \texttt{Cons} with the operator \texttt{op}. The recursive occurrence of \texttt{List a} in the datatype definition is replaced by a recursive call to \texttt{cata_L} in the function definition. In the general case every constructor in the definition of the datatype is replaced by a function of the same arity\(^1\) and recursive datatypes are transformed to recursive functions with exactly the same structure.

Now the definition of cata_T is straightforward; we just replace \texttt{Leaf} by a function \texttt{f} and \texttt{Bin} by a binary operator \texttt{op}:

| data Tree a = | cata_T :: (a -> b) -> (b -> b -> b) -> Tree a -> b  
| Leaf a           | cata_T f op (Leaf x) = f x  
| Bin (Tree a) (Tree a) | cata_T f op (Bin l r) = op (ca l) (ca r)  
where ca = cata_T f op |

FIGURE 4.  
The definition of the catamorphism for binary trees.

Despite the simplicity of the definition, this is a very sophisticated higher order function with which we can define many other functions. Informally a catamorphism can calculate anything for a structure that can be calculated given the information in the top node and the result of the catamorphism on all substructures.

---

1. The arity of a function is the number of arguments it takes. We will consider constants to be functions with arity zero.
Some examples are:

\[
\text{map}_T :: (a \rightarrow b) \rightarrow \text{Tree } a \rightarrow \text{Tree } b
\]

\[
\text{map}_T \ f = \text{cata}_T (\text{Leaf} \ . \ f) \ \text{Bin}
\]

```
-- This definition is equivalent to the one above.
```

\[
\text{flatten}_T :: \text{Tree } a \rightarrow [a]
\]

\[
\text{flatten}_T = \text{cata}_T \ \text{wrap} \ (++)
\]

```
where \text{wrap} \ x = [x]
```

```
-- The structure is flattened to a list.
```

\[
\text{unzip}_T :: \text{Tree } (a,b) \rightarrow (\text{Tree } a, \text{Tree } b)
\]

\[
\text{unzip}_T = \text{cata}_T (\text{prod} \ (\text{Leaf}, \text{Leaf})) \ (\text{prod} \ . \ \text{prod} \ (\text{Bin}, \text{Bin}))
\]

```
where \text{prod} \ (f,g) \ (a,b) = (f \ a, g \ b)
```

```
-- Takes a tree of pairs and returns a pair of trees.
```

\[
\text{size}_T :: \text{Tree } a \rightarrow \text{Int}
\]

\[
\text{size}_T = \text{cata}_T (\text{const} \ 1) \ (\lambda l \ r \rightarrow 1+l+r)
\]

```
-- Counts the number of constructors.
```

\[
\text{depth}_T :: \text{Tree } a \rightarrow \text{Int}
\]

\[
\text{depth}_T = \text{cata}_T (\text{const} \ 0) \ (\lambda l \ r \rightarrow 1+(\text{max} \ l \ r))
\]

```
-- Calculates the maximal level of the constructors.
```

\[
\text{leftmost}_T :: \text{Tree } a \rightarrow a
\]

\[
\text{leftmost}_T = \text{cata}_T \ \text{id} \ \text{const}
\]

```
-- returns the leftmost element of the tree.
```

\[
\text{mirror}_T :: \text{Tree } a \rightarrow \text{Tree } a
\]

\[
\text{mirror}_T = \text{cata}_T \ \text{Leaf} \ (\text{flip} \ \text{Bin})
\]

```
-- Mirrors the tree in a line through its root.
```

Except for the last one (that depends on the fact that the two arguments to \text{Bin} are of the same type) all these functions can be generalised to all tree types.

Using a catamorphism for that datatype lots of functions from a datatype to something else can be written. A simple example of a function that is not a catamorphism is \text{tail} that gives the tail of a list. For \text{tail} to be a catamorphism we would need a function that could calculate \text{tail} \ (x:xs) from \text{x} and \text{tail} \ xs which is clearly impossible since the information about the first element of \text{xs} is lost.

### 2.3 Functors

The recursive definitions of the two types in the previous section can be thought of as being the fixpoints with respect to the parameter \(x\) of these two types:

\[
\text{data } \text{FList } x \ a = \text{FNil}
\]

```
| \text{FCons } a \ x
```

\[
\text{data } \text{FTree } x \ a = \text{FLeaf } a
\]

```
| \text{FBin } x \ x
```

The structure of these types and the names of the constructors is all that is needed to generate \text{map}, \text{cata} and other polytypic functions. When dealing with these functions theoretically it is useful to go one step further and ignore the actual names of the constructors retaining only the structure, as all datatypes that differ only in the names of the constructors are isomorphic. This stripped structure of the type will be called a functor\(^1\).
By ignoring the specific constructor names we get for \texttt{List} the functor 
\[ L \times a = 1 + a \times x, \]  
and for \texttt{Tree} we get \[ T \times a = a + a \times x. \]  
Here the arguments \( a \) and \( x \) can be thought of as sets, the sum means disjoint union of sets and the product is the cross product.

The concept of functors is essential to the underlying theory of polytypism and almost all polytypic functions are defined either using induction on the structure functors or by combining other polytypic functions. This means that it is very important to have a sufficiently rich structure representing functors, as the polytypic functions we define will work only for the types that we can represent by fixpoints of functors.

In the system functors are represented as elements of the datatype \texttt{Func}:

\begin{verbatim}
data Func a =
  Prod [Func a] -- direct product of functors
  Sum [Func a] -- sum of functors
  Comp a [Func a] -- composition of a constructor
                   --   with a list of functors
  Par Int Int     -- type parameter, first the position
                   --   number in the mut. rec. group
                   --   then the local argument number
  Rec Int         -- recursive parameter
\end{verbatim}

For a functor representing a datatype in Haskell the top level is always a \texttt{Sum} with a list of functors representing the alternatives, one for each constructor in the type. Each of these alternatives is a \texttt{Prod} with a list of the representations of the arguments of the corresponding constructor. For \texttt{List} and \texttt{Tree} we get:

\begin{verbatim}
funcList = Sum [Prod [],
               Prod [Par 1 1, Rec 1]]

funcTree = Sum [Prod [Par 1 1],
                Prod [Rec 1, Rec 1]]
\end{verbatim}

The second argument to \texttt{Par} is the position of the corresponding parameter in the type’s argument list, and as both these types only have one argument it is 1. The first argument to \texttt{Par} and the only argument to \texttt{Rec} is 1 for all directly recursive (as opposed to the mutually recursive) types.

---

1. A functor is mathematically a function between categories that preserves the algebraic structure of the category. As such they can be applied to both functions (arrows) and datatypes (objects) [13].
As an example of a group of mutually recursive datatype definitions we can take Zig and Zag defined by:

```haskell
data Zig a b = Blib
  | Ping a (Zag a b)
data Zag a b = Blob
  | Pong b (Zig a b)
```

By replacing the right hand side recursive references to Zig a b and Zag a b by Rec 1 and Rec 2 respectively we get:

```haskell
funcZig = Sum [Prod [],
  Prod [Par 1 1, Rec 2] ]
funcZag = Sum [Prod [],
  Prod [Par 2 2, Rec 1] ]
```

Finally Comp is used when a type definition refers to another type which does not itself refer back to the first type. (That is, these two types are not in the same mutual recursive group.) A typical example of this is rose trees:

```haskell
data Rose a = Fork a (List (Rose a))
funcRose = Sum [Prod [Par 1 1,
  Comp "List" [Rec 1] ] ]
```

It is important to note here that not all types can be represented by a functor in the system. The datatypes we can handle do not include function spaces (though it could be included in this formalism, see [12]) and requires that recursive occurrences of the datatype be exactly equal to the left hand sides of the definitions. But as we have seen it does handle ordinary tree types including mutual recursive ones. Two examples of types that we can not handle are:

```haskell
data Zigzag a b = Bliob | Piong a (Zigzag b a)
data Strange a = This a | That (Strange (a,a))
```

The first example has a recursive reference to itself which is not identical to the left hand side, but this can be worked around by instead using the pair of mutually recursive types Zig and Zag above. The second example is worse, even trying to define a map by hand on this type fails in Haskell.

```haskell
map_Strange f (This x) = This (f x)
map_Strange f (That s) = That (map_Strange (prod f f) s)
  where prod f g (a,b) = (f a,g b)
```

Intuitively this is what a map on this type should do, but the problem is that map_Strange is used on different types on the left and right hand side which gives us an error message from the type checker.
3 Basic polytypic functions

To be able to reason about functional programs in a more mathematical style we will try to write functions with a limited number of combinators, standard functions and types. The following sections will describe how most of the functions generated by the system work and how they can be used.

3.1 Predefined functions and types

We use a number of families of functions indexed by integers where each family would preferably be implemented as one function taking this index as its first argument. As the Haskell type system doesn’t support the types such functions would have we have implemented these function families by just extending the families names with integers. In the following we will still use the index notation but only as a more readable form of just extending the name with the number. (so \texttt{prod}_3 will mean \texttt{prod3}.)

3.1.1 Products

The first function families comes together with a type that is predefined in most functional languages; the tuple or product type. We define type synonyms the get type constructors for all tuples.

\[
\text{Prod}_n :: a_1 \rightarrow \ldots \rightarrow a_n \rightarrow (a_1, \ldots ,a_n)
\]

\[
\text{type Prod}_n a_1 \ldots a_n = (a_1, \ldots ,a_n)
\]

To easily write functions from a tuple to a tuple we also define

\[
\text{prod}_n :: (a_1\rightarrow b_1) \rightarrow \ldots \rightarrow (a_n\rightarrow b_n) \rightarrow \\
\text{Prod}_n a_1 \ldots a_n \rightarrow \text{Prod}_n b_1 \ldots b_n
\]

\[
\text{prod}_n f_1 \ldots f_n (x_1, \ldots ,x_n) = (f_1 x_1, \ldots ,f_n x_n)
\]

which can be seen as the map for the type \text{Prod}_n as it takes one function for every type parameter and applies that function to the corresponding argument.

As a generalisation of \texttt{uncurry} :: (a \rightarrow b \rightarrow c) \rightarrow (a,b) \rightarrow c we define

\[
\text{uncurry}_n :: (a_1 \rightarrow \ldots \rightarrow a_n \rightarrow b) \rightarrow \text{Prod}_n a_1 \ldots a_n \rightarrow b
\]

\[
\text{uncurry}_n f (x_1, \ldots ,x_n) = f x_1 \ldots x_n
\]

which can be seen as the catamorphism on tuples where the tuple constructor \texttt{Prod}_n is replaced by the function \texttt{f}.

The last tuple-related function \texttt{split} which builds a tuple from any type and thus can be seen as the anamorphism on tuples:

\[
\text{split}_n :: (a\rightarrow b_1) \rightarrow \ldots \rightarrow (a\rightarrow b_n) \rightarrow a \rightarrow \text{Prod}_n b_1 \ldots b_n
\]

\[
\text{split}_n f_1 \ldots f_n x = (f_1 x, \ldots ,f_n x)
\]
3.1.2 Sums
To represent a choice between different alternatives we will use the type \( \text{Sum}_n \) defined by

\[
\text{data Sum}_n a_1 \ldots a_n = \text{In}_{n1} a_1 \mid \ldots \mid \text{In}_{nn} a_n
\]

We will identify \( \text{Sum}_1 a \) with \( a \) and \( \text{In}_{11} x \) with \( x \).

The map on this type is

\[
\text{sum}_n :: (a_1 \to b_1) \to \ldots \to (a_n \to b_n) \to \\
\text{Sum}_n a_1 \ldots a_n \to \text{Sum}_n b_1 \ldots b_n
\]

\[
\text{sum}_n f_1 \ldots f_n = s
\]

where \( s (\text{In}_{n1} x) = \text{In}_{n1} (f_1 x) \)

\[
\ldots
\]

\[
s (\text{In}_{nn} x) = \text{In}_{nn} (f_n x)
\]

The function \( \text{join}_n \) that joins all the \( n \) cases together to one resulting type is defined by

\[
\text{join}_n :: (a_1 \to b) \to \ldots \to (a_n \to b) \to \\
\text{Sum}_n a_1 \ldots a_n \to b
\]

\[
\text{join}_n f_1 \ldots f_n = j
\]

where \( j (\text{In}_{n1} x) = f_1 x \)

\[
\ldots
\]

\[
j (\text{In}_{nn} x) = f_n x
\]

This can be seen as the catamorphism on \( \text{Sum}_n \) as the constructors \( \text{In}_{ni} \) are replaced by \( f_i \) for all \( i \).

The composition of a sum and a join can be simplified to just a join: (For brevity we here introduce a vector notation defined in the next section.)

\[
\text{join}_n f \cdot \text{sum}_n a = \text{join}_n (f, a)
\]

3.2 Notation
Polytypic functions will be written with an index specifying what type they work on as in \( \text{map}_{\text{Tree}} \). In the system this is written \( \text{mapTree} \) but we will use the index notation as a remainder that we think about polytypic functions as functions taking a type as first argument and that the actual implementation is just a way of simulating this behaviour.

Normally we will work with an unspecified example type \( D a_1 \ldots a_n \):

\[
\text{data } D a_1 \ldots a_n = C_1 e_{1,1} \ldots e_{k_1,1} \\
| \ldots \\
| C_n e_{1,n} \ldots e_{k_n,n}
\]
Here the $C_i$ are type constructors, $e_{i,j}$ are type expressions using the type parameters $a_1 \ldots a_n$ and $k_1$ to $k_n$ are the arities of the constructors $C_1$ to $C_n$. This type is not mutually recursive to make the examples easier to read, but all functions described in this chapter works also for groups of mutually recursive types\(^1\). For readability we will in some examples use a vector notation and write $\mathbf{a}$ instead of $a_1 \ldots a_n$ where $n$ always will be the number of type parameters of the type $D$. This vector notation is also used for composition, pair forming, etc. The following examples, where $n=3$ and $D=\text{Test}$, shows the intended interpretation of this:

<table>
<thead>
<tr>
<th>short form</th>
<th>stands for</th>
</tr>
</thead>
<tbody>
<tr>
<td>$f_1 \mathbf{a}$</td>
<td>$f_1 \ a_1 \ a_2 \ a_3$</td>
</tr>
<tr>
<td>$\text{map}_D \ f . g$</td>
<td>$\text{mapTest} (f_1 . g_1) (f_2 . g_2) (f_3 . g_3)$</td>
</tr>
<tr>
<td>$f_D \ c \mathbf{g}$</td>
<td>$f_{\text{Test}} \ c \ f_1 \ f_2 \ f_3 . \ g$</td>
</tr>
<tr>
<td>$D (a,b)$</td>
<td>$\text{Test} (a_1,b_1) (a_2,b_2) (a_3,b_3)$</td>
</tr>
</tbody>
</table>

### 3.3 Object and arrow

Mathematically a functor is a function that can be applied to objects (types) and arrows (functions). To simulate this behaviour we provide for each functor one type $F_D$ (which can be seen as a function from its type parameters to a type) and one function $f_D$.

The datatype $F_D$ has exactly the same structure as the functor. This means that it has the same structure as the type $D$ with a recursive parameter added which is used in place of the recursive references. (See the examples in section 2.3) The right hand side of the type definition is generated by a catamorphism on the type $\text{Func}$ where the constructor $\text{Sum}$ in $\text{Func}$ is replaced by the code calling $\text{Sum}_n$, $\text{Prod}$ by a call to $\text{Prod}_{k_1}$, $\text{Comp}$ by a call to the referred type and $\text{Rec}$ and $\text{Par}$ by their corresponding parameters from the left hand side. We get something of the form:

$$
type F_D \ r \mathbf{a} = \text{Sum}_n (\text{Prod}_{k_1} t_{1,1} \ldots t_{1,k_1})$$

$$
\quad \ldots$$

$$
\quad \text{(Prod}_{k_n} t_{n,1} \ldots t_{n,k_n})$$

where $t_{i,j}$ is the result of this catamorphism on $e_{i,j}$.

The function $f_D$ is the map on the type $F_D$ and will therefore also denoted by $\text{map}_{F_D}$. Its structure is also very similar to that of the functor and it is defined by a catamorphism on the type $\text{Func}$ with almost the same arguments as the cata for $F_D$. The difference is that, as we generate a map here, we change the calls to the type

---

1. In appendix A the code for all functions generated by the system is shown for a mutually recursive pair of types.
Basic polytypic functions

collectors to calls to the maps over those type constructors. The function definition has the form:

\[
f_D : (ra \rightarrow rb) \rightarrow (a_1 \rightarrow b_1) \rightarrow \ldots \rightarrow (a_n \rightarrow b_n) \rightarrow F_D ra a \rightarrow F_D rb b
\]

\[
f_D r a = \text{sum}_n (\text{prod}_{k_1} g_{1,1} \ldots g_{1,k_1})
\]

\[
\ldots
\]

\[
(\text{prod}_{k_n} g_{n,1} \ldots g_{n,k_n})
\]

We exemplify this for two datatypes; for List we get:

\[
\text{--funcList} = \text{Sum} \left[ \text{Prod } [], \text{Prod } [\text{Par } 1 \ 1, \text{Rec } 1] \right]
\]

\[
\text{type } F_{\text{List}} ra a = \text{Sum}_2 () (a,ra)
\]

\[
f_{\text{List}} rg g = \text{sum}_2 \text{prod}_0 (\text{prod}_2 g rg)
\]

and for Rose we get: (remember that we have identified \(\text{Sum}_1 a\) with \(a\))

\[
\text{--data Rose a = Fork a (List (Rose a))}
\]

\[
\text{--funcRose} = \text{Sum} \left[ \text{Prod } [\text{Par } 1 \ 1, \text{Comp } \text{"List" } [\text{Rec } 1] ] \right]
\]

\[
\text{type } F_{\text{Rose}} ra a = (a,(\text{List } ra))
\]

\[
f_{\text{Rose}} rg g = (\text{prod}_2 g (\text{map}_{\text{List}} rg))
\]

### 3.4 In and out

We define a function \(\text{out}_D\) so that the pattern matching for all the cases of the type \(D\) \(a\) is done by this function once and for all. \(\text{out}_D\) strips off the constructors from the top level of a value of type \(D\) \(a\) replacing them by Sums and Prods.

\[
\text{out}_D :: D\ a \rightarrow F_D (D\ a)\ a
\]

\[
\text{out}_D (C_1\ x_1 \ldots x_{k_1}) = \text{In}_{n_1} (x_1, \ldots, x_{k_1})
\]

\[
\ldots
\]

\[
\text{out}_D (C_n\ x_1 \ldots x_{k_n}) = \text{In}_{n_n} (x_1, \ldots, x_{k_n})
\]

It is important to note that the \(\text{out}_D\) is not recursive and that the substructures of the result can be of the types \(a\) and \(D\ a\). As an example we can take \(\text{out}\) for the type List:

\[
\text{out}_{\text{List}} :: \text{List}\ a \rightarrow F_{\text{List}} (\text{List}\ a)\ a
\]

\[
\text{out}_{\text{List}} (\text{Nil}) = \text{In}_{21} ()
\]

\[
\text{out}_{\text{List}} (\text{Cons } x \ xs) = \text{In}_{22} (x,xs)
\]

The dual function \(\text{in}_D\) does the opposite of \(\text{out}_D\); it puts back all the correct constructors to create a value of the type \(D\). It is so to say the constructor of the type \(D\) as it is a join of the different constructors.

\[
\text{in}_D :: F_D (D\ a)\ a \rightarrow D\ a
\]

\[
\text{in}_D = \text{join}_n (\text{uncurry}_{k_1} C_1) \ldots (\text{uncurry}_{k_n} C_n)
\]
Here we can see the real use of the predefined functions letting us write \( \text{in}_D \) in a concise way without any pattern matching. \( \text{join} \) matches the cases of the top level \( \text{sum} \) and \( \text{uncurry} \) makes the constructors applicable to tuples. As examples we show \( \text{in} \) for \( \text{List} \) and \( \text{Rose} \):

\[
\begin{align*}
\text{in}_{\text{List}} &= \text{join}_2 \ (\text{const Nil}) \ (\text{uncurry}_2 \ \text{Cons}) \\
\text{in}_{\text{Rose}} &= \text{uncurry}_2 \ \text{Fork}
\end{align*}
\]

Both \( \text{in}_D \) and \( \text{out}_D \) are isomorphisms, and they are each others inverses:

\[
\text{in}_D \ . \ \text{out}_D = \text{id} = \text{out}_D \ . \ \text{in}_D
\]

### 3.5 Map

The map on a datatype \( D \) is a higher order function taking as many functions as arguments as the type has type parameters. When the resulting function \( m \) is applied to an object of type \( D \), each of these argument functions is applied to all occurrences of elements of their specific type leaving the structure of the object unchanged.

\[
\begin{align*}
\text{map}_D :: (a_1 -> b_1) \rightarrow \ldots \rightarrow (a_n -> b_n) \rightarrow \\
D \ a_1 \ldots \ a_n \rightarrow D \ b_1 \ldots \ b_n
\end{align*}
\]

\[
\text{map}_D \ g_1 \ldots \ g_n = m
\]

where \( m = \text{in}_D \ . \ ( f_D \ m \ g_1 \ldots \ g_n ) \ . \ \text{out}_D \)

\[
\begin{align*}
m :: D \ a \rightarrow D \ b \\
\text{out}_D :: D \ a \rightarrow F_D (D \ a) \ a \\
f_D \ m \ g :: F_D (D \ a) \ a \rightarrow F_D (D \ b) \ b \\
in_D :: F_D (D \ b) \ b \rightarrow D \ b
\end{align*}
\]

The function \( m \) first removes the constructors with \( \text{out}_D \). Then, using \( f_D = \text{map}_D \), \( m \) is called recursively for all occurrences of the recursive argument in \( F_D \). Finally \( \text{in}_D \) injects the resulting object into the type \( D \) again.

It is instructive to compare what this definition will give us for \( \text{Tree} \) with the intuitive definition of \( \text{map}_T \) in section 2.1. (The following is a calculation, not a definition.)

\[
\begin{align*}
\text{map}_\text{Tree} \ f \ m &= \text{in}_\text{Tree} \ . \ f_\text{Tree} \ m \ f \ . \ \text{out}_\text{Tree} \\
&\{ \text{Insert the definitions of in and f} \}
\end{align*}
\]

\[
\begin{align*}
\text{join}_2 \ \text{Leaf} \ (\text{uncurry}_2 \ \text{Bin}) \ . \ \text{sum}_2 \ f \ (\text{prod}_2 \ m \ m) \ . \ \text{out}_\text{Tree} \\
&\{ \text{Use a law for join and sum: join}_n \ f \ . \ \text{sum}_n \ g \ = \ \text{join}_n \ f . g \}
\end{align*}
\]

\[
\begin{align*}
\text{join}_2 \ (\text{Leaf} . f) \ (\text{uncurry}_2 \ \text{Bin}) \ . \ \text{prod}_2 \ m \ m) \ . \ \text{out}_\text{Tree} \\
&\{ \text{Use a law for uncurry and prod:}
\end{align*}
\]

\[
\begin{align*}
\text{uncurry}_n \ f \ . \ \text{prod}_n \ g \ = \ (\text{\Prod}_n \ a \rightarrow f \ g \ a) \\
\text{join}_2 \ (\text{Leaf} . f) \ (\\{x_1, x_2\} \rightarrow \text{Bin} \ (m \ x_1) \ (m \ x_2)) \ . \ \text{out}_\text{Tree}
\end{align*}
\]
Basic polytypic functions

The \texttt{join} together with the \texttt{out} on the far right is equivalent to pattern matching on the left so we get:

\begin{verbatim}
map_{Tree} f = m
  where m (Leaf x) = Leaf (f x)
        m (Bin x1 x2) = Bin (m x1) (m x2)
\end{verbatim}

which can be compared with \texttt{map\_T} from section 2.1:

\begin{verbatim}
map\_T f (Leaf x) = Leaf (f x)
map\_T f (Bin l r) = Bin (map\_T f l) (map\_T f r)
\end{verbatim}

\subsection*{3.6 Cata}

The catamorphism is, like map, a higher order function, but it takes only one argument\(^1\) instead of one for each parameter.

The definition of the catamorphism is similar to the definition of map; first \texttt{out\_D} is used to remove the constructors, then \texttt{f\_D} applies the catamorphism to the recursive substructures. The difference is that here we leave the values on the top level unchanged by using \texttt{id} in the call to \texttt{f\_D} and, most importantly, we insert the values into another type than \texttt{D} by using the argument function \texttt{i} instead of \texttt{in\_D}.

\begin{verbatim}
cata_{D} ::= (F\_D b \_a -> b) -> D \_a -> b
cata_{D} i = c
  where c = i . (f_{D} c \texttt{id}) . out_{D}
    c :: D \_a -> b
    out_{D} :: D \_a -> F\_D (D \_a) \_a
    f_{D} c \texttt{id} :: F\_D (D \_a) \_a -> F\_D b \_a
    i :: F\_D b \_a -> b
\end{verbatim}

Here \texttt{id} means \(n\) copies of the identity function.

Note that we could have defined \texttt{map} using \texttt{cata}:

\begin{verbatim}
map_{D} ::= (a_{1}\_->b_{1}) -> ... -> (a_{n}\_->b_{n}) -> D \_a -> D b
map_{D} g = cata_{D} i
  where i = in_{D} . f_{D} \texttt{id} g
    i :: F\_D (D b) \_a -> D b
    f_{D} \texttt{id} g :: F\_D (D b) \_a -> F\_D (D b) \_b
    in_{D} :: F\_D (D b) \_b -> D b
\end{verbatim}

This is equivalent to the definition in section 3.5 but slightly less efficient.

---

1. Actually, for a group of mutually recursive types, the catamorphism (for all types) takes one argument function for each type in the group.
3.7 Ana

The anamorphism is the dual of the catamorphism in the sense that everything in the definition of \( \text{ana} \) has the same types as in the definition of \( \text{cata} \) except that all arrows are reversed.

\[
\text{ana}_D :: (b \rightarrow F_D b a) \rightarrow b \rightarrow D a
\]

\[
\text{ana}_D o = a
\]

where \( a = \text{in}_D \) . (\( f_D a id \)) . o

\[
a :: b \rightarrow D a
\]

\[
o :: b \rightarrow F_D b a
\]

\[
f_D a id :: F_D b a \rightarrow F_D (D a) a
\]

\[
\text{in}_D :: F_D (D a) a \rightarrow D a
\]

The anamorphism can be used to build elements of a type from something else. As an example we can build perfect trees of depth \( d \) filled with an element \( x \) by using the \( \text{ana} \) on \( \text{Tree} \):

\[
\text{ana}_{\text{Tree}} :: (b \rightarrow F_{\text{Tree}} b a) \rightarrow b \rightarrow \text{Tree} a
\]

If we take the argument to the resulting function to be a pair of the desired depth and the element to fill with we get \( b = (\text{Int},a) \) so that

\[
F_{\text{Tree}} b a = \text{Sum}_2 a (b,b) = \text{Sum}_2 a ((\text{Int},a),(\text{Int},a))
\]

\[
o :: (\text{Int},a) \rightarrow \text{Sum}_2 a ((\text{Int},a),(\text{Int},a))
\]

\[
o (0 ,x) = \text{In}_{21} x
\]

\[
o (n+1,x) = \text{In}_{22} ( (n,x) , (n,x) )
\]

\[
\text{perf} = \text{ana}_{\text{Tree}} o :: (\text{Int},a) \rightarrow \text{Tree} a
\]

\[
\text{perf} (2,’a’) = \text{Bin} ( \text{Bin} (\text{Leaf} ’a’) (\text{Leaf} ’a’) )
\]

\[
( \text{Bin} (\text{Leaf} ’a’) (\text{Leaf} ’a’) )
\]

3.8 Hylo

Often a programming problem can be solved using an intermediate type \( D \) such that we first construct an element of \( D \) using \( \text{ana}_D \) and then build the result by destructing this element with \( \text{cata}_D \). The resulting program is a composition of a catamorphism with an anamorphism. This composition can be simplified by unfolding the definitions of \( \text{cata} \) and \( \text{ana} \):

\[
\text{cata}_D i \ . \ \text{ana}_D o = c \ . \ a = \{ \text{the definitions of cata and ana} \}
\]

\[
i . (f_D c \ id) \ . \ \text{out}_D \ . \ \text{in}_D \ . \ (f_D a \ id) \ . \ o = \{ \text{out}_D \ . \ \text{in}_D == id \}
\]

\[
i . (f_D c \ id) \ . \ (f_D a \ id) \ . \ o = \{ f_D == \text{map}_F, \text{property of all maps: map } f \ . \ \text{map } g == \text{map } f.g \}
\]

\[
i . (f_D (c \ . \ a) \ id) \ . \ o
\]
This composition is a hylomorphism:

\[
\text{hylo}_D :: (F_D c a \to c) \to (b \to F_D b a) \to b \to c
\]

\[
\text{hylo}_D i o = h
\]

where \( h = i \cdot (f_D h \text{id}) \cdot o \)

\[
\begin{align*}
h &: b \to c \\
o &: b \to F_D b a \\
f_D h \text{id} &: F_D b a \to F_D c a \\
i &: F_D c a \to c
\end{align*}
\]

As we can see from the type, the hylomorphism never really refers to the datatype \( D \) directly; using a hylomorphism is using a virtual datastructure.

The cata- and anamorphisms can be defined as special cases of the hylomorphism where

\[
\text{cata}_D i = \text{hylo}_D i \text{ out}_D \\
\text{ana}_D o = \text{hylo}_D \text{ in}_D o
\]

### 3.9 Flatten

We now have the necessary basis to go on to define more specific polytypic functions. By flattening an element of a datatype \( D \) with respect to a type parameter \( a_i \) we mean making a list of all occurrences of values of the type \( a_i \) in the element. As this is a function from \( D \) to a list it is natural to try to use a catamorphism to define it. For this to be possible we must construct a function (the argument \( i \) to \( \text{cata}_D \)) that, given the flattened substructures and the data in the top level nodes, calculates the resulting list. Intuitively this is done by simply concatenating all sublists and prepending all elements in the top level. This is not much worse in practice though one has to keep track of some indices.

We will call the generated functions \( f_{D1} \ldots f_{Dn} \) where

\[
\begin{align*}
f_{D1} :: & D \tilde{a} \to [a_i] \\
f_{D1} &= \text{cata}_D f_1
\end{align*}
\]

where \( f_1 = \text{cup} f_{FD1} (\text{concat} f_{FD1}) \)

\[
\begin{align*}
f_1 :: &= F_D [a_i] \tilde{a} \to [a_i] \\
f_{FD1} :: &= F_D [a_i] \tilde{a} \to [a_i] \\
f_{FD1} :: &= F_D [a_i] \tilde{a} \to [[a_i]] \\
cup f g x &= (f x) ++ (g x)
\end{align*}
\]
Here we have used flatten on the nonrecursive type $F_D$ with respect to $a_i$ (this is $\text{fl}_{F_D}$) and with respect to the parameter representing the recursive argument ($\text{fl}_{F_D^r}$ where $r$ is the letter $r$ and not an index variable).

\[\text{fl}_{F_D^1} :: F_D b a \rightarrow [a_i]\]
\[\text{fl}_{F_D^r} :: F_D b a \rightarrow [b]\]

The functions $\text{fl}_{F_D}$ are defined by induction over the structure of the functor which means that the definition can be generated by a catamorphism on $\text{Func}$ with suitable arguments.

3.10 Partial functions

For the definition of zip we will need to deal with partial functions. For this purpose we introduce the type $\text{Maybe}$ (defined by $\text{data Maybe a = No } | \text{ Yes a}$) and implement partial functions as functions returning $\text{Yes x}$ for arguments where they are well defined and $\text{No}$ otherwise. Composition of partial functions is strict in $\text{No}$ and is written with the function $\text{cmp}$. We also provide $\text{partfun}$, a simple way of defining a partial function from a predicate and a normal function.

\[\text{cmp} :: (b \rightarrow 1+ c) \rightarrow (a \rightarrow 1+ b) \rightarrow a \rightarrow 1+ c\]
\[\text{cmp } f \ g \ x = \text{ case } g \ x \text{ of}\]
\[\text{No} \rightarrow \text{No}\]
\[(\text{Yes } x) \rightarrow f \ x\]

\[\text{partfun} :: (a \rightarrow \text{Bool}) \rightarrow (a \rightarrow b) \rightarrow a \rightarrow 1+ b\]
\[\text{partfun } p \ f \ x \mid p \ x = \text{Yes } (f \ x)\]
\[= \text{No}\]

We will usually write the type $\text{Maybe a}$ as $1+ a$.

The polytypic function $\text{prop}_D$ is used to propagate $\text{No}$ out of the type $D$. This means that if there is a $\text{No}$ somewhere in an element $e$ of $1+ a$ the value of $\text{prop}_D e$ is $\text{No}$, and otherwise it is $\text{Yes } e'$ where $e'$ is $e$ with all occurrences of $\text{Yes } x$ replaced by just $x$.

\[\text{prop}_D :: D 1+ a \rightarrow 1+ D a\]
\[\text{prop}_D = \text{cata}_D p\]
where $p = (\text{Yes } . \text{ in}_D)' \text{ cmp } \text{ prop}_D$
\[p :: F_D (1+ D a) 1+ a \rightarrow 1+ D a\]
\[\text{prop}_D :: F_D (1+ D a) 1+ a \rightarrow 1+ F_D (D a) a\]
\[\text{Yes } . \text{ in}_D :: F_D (D a) a \rightarrow 1+ D a\]
\[\text{prop}_D :: F_D (1+ a) 1+ b \rightarrow 1+ F_D a b\]

1. The functor representing the type $\text{Maybe}$ is $M a = 1+ a$ or just $M = 1+$. 
We define a partial function hylomorphism \texttt{parthylo} that works as a normal hylomorphism for \texttt{Yes} values and propagates \texttt{No} values up to the top level.

\texttt{parthylo} \_D \:: (\texttt{F} \_D \texttt{c} \_a \rightarrow 1+ \_c) \rightarrow (\texttt{b} \rightarrow 1+ \texttt{F} \_D \_b \_a) \rightarrow \texttt{b} \rightarrow 1+ \texttt{c}

\texttt{parthylo} \_D \texttt{pi} \_\texttt{po} = \texttt{ph}

where \texttt{ph} = \texttt{pi} \texttt{'}cmp\texttt{'} \texttt{(prop}_{\texttt{FD}} \_\texttt{f} \_\texttt{ph} \_\texttt{pid}) \texttt{'}cmp\texttt{'po}

\texttt{ph} \:: \texttt{b} \rightarrow 1+ \texttt{c}

\texttt{po} \:: \texttt{b} \rightarrow 1+ \texttt{F} \_D \texttt{b} \_a

\texttt{f} \_\texttt{ph} \_\texttt{pid} :: \texttt{F} \_D \texttt{b} \_a \rightarrow \texttt{F} \_D (1+ \texttt{c}) 1+ \_a

\texttt{prop}_{\texttt{FD}} :: \texttt{F} \_D (1+ \texttt{c}) 1+ \_a \rightarrow 1+ \texttt{F} \_D \_c \_a

\texttt{pi} :: \texttt{F} \_D \_c \_a \rightarrow 1+ \texttt{c}

As we mentioned in section 3.8 (where \texttt{hylo} is defined), \texttt{cata} and \texttt{ana} can be very easily defined by using \texttt{hylo} and analogously we can define the partial function version of \texttt{ana} using \texttt{parthylo}:

\texttt{parana}_D :: (\texttt{b} \rightarrow 1+ \texttt{F} \_D \_b \_a) \rightarrow \texttt{b} \rightarrow 1+ \_D \_a

\texttt{parana}_D \texttt{ro} = \texttt{parthylo}_D \_\texttt{(Yes.in}_0\texttt{)} \_\texttt{ro}

### 3.11 Zip

The normal zip on lists takes two lists and return a list of pairs where the i:th pair contains the i:th element from both lists. The polytypic zip takes a pair of structures to a structure of pairs. The problem with this is that for a general datatype this operation is well defined only if the elements have exactly the same form. For lists this is often handled by just truncating the longer list but for a general type it is not clear how this truncating should be done. It is, for example, impossible to zip the tree \texttt{Leaf} \_x with \texttt{Bin} \_l \_r. We have therefore chosen to define zip as a partial function:

\texttt{zip}_D :: (\texttt{D} \_a, \texttt{D} \_b) \rightarrow 1+ \texttt{D} \_\{a,b\}

If it had not been for \texttt{1+} on the right hand side this would be a typical case for a normal anamorphism as \texttt{zip} builds values of type \texttt{D}. As we know that \texttt{zip} is strict in \texttt{No} we can instead define \texttt{zip} by a partial function anamorphism.

\texttt{zip}_D = \texttt{parana}_D \texttt{z}

where \texttt{z} = \texttt{zip}_{\texttt{FD}} \cdot \texttt{prod}_2 \_\texttt{out}_D \_\texttt{out}_D

\texttt{z} :: (\texttt{D} \_\{a,b\}) \rightarrow 1+ \texttt{F} \_D (\texttt{D} \_\{a,b\} \_\{a,b\})

\texttt{zip}_{\texttt{FD}} :: (\texttt{F} \_D \_a \_\{b\}, \texttt{F} \_D \_c \_\{d\}) \rightarrow 1+ \texttt{F} \_D \_\{a,c\} \_\{b,d\}

The zip on the functor (\texttt{zip}_{\texttt{FD}}) can be defined by induction over the structure of the functor and thus it can be generated by a catamorphism on the type \texttt{Expr}. As an example of one of these cases we show the zip for a tuple:

\texttt{zipProd}_n ((\texttt{a}_1,\ldots,\texttt{a}_n),(\texttt{b}_1,\ldots,\texttt{b}_n)) = \texttt{Yes} ((\texttt{a}_1,\texttt{b}_1),\ldots,(\texttt{a}_1,\texttt{b}_1))
4 Program construction combinators

In the system we need function builders that given a functor generate the code for that specific instance of a polytypic function. To simplify writing a function builder starting with a description of a polytypic function in the notation of section 3 we will in this section describe a number of code combinators and basic code-building blocks.

4.1 A combinator example

As an example of the use of the program construction combinators, consider the definition of \( \text{cata} \) for some type \( D \): \( \text{cata}_D f = f . f _D (\text{cata}_D f) \text{id} . \text{out}_D \)

With the combinators the program code generating this function definition can be written as:

\[
\text{ca} = f \cdot (\text{arc } d \cdot [\text{ca}, \text{idc}]) \cdot (\text{outc } d) \\
\text{where ca} = \text{catac } d \cdot [f] \\
\text{arc } d = q ("f" + +d) \\
\text{outc } d = q ("out" + +d) \\
\text{catac } d = q ("\text{cata}" + +d) \\
\text{idc} = q "\text{id}" \\
f = q "f" 
\]

provided \( d \) is the name of the datatype.

In the following sections we will describe the combinators \(-., \cdot., \cdot@\) and the basic building blocks \( \text{arc}, \text{outc}, \ldots \) in more detail.

4.2 Basic building blocks

Here we have shorthand notation for the code representing many common functions; \( \text{id} \) is generated by \( \text{idc} \), const by \( \text{constc} \) and so on. To give the possibility to use functions not included here there is also a function \( \text{quote} \) or just \( q \) that embeds any string in the code. The type \( \text{Expr} \) that is used to represent the expressions is defined in section 5.3.

\[
\text{idc} :: \text{Expr String} \\
q :: a \rightarrow \text{Expr a} 
\]

4.3 Binary combinators

The basic building blocks are put together to expressions with operators for composition (\(-\cdot\)) and application (\(-@\)).

\[
(-.) :: \text{Expr a} \rightarrow \text{Expr a} \rightarrow \text{Expr a} \\
(-@) :: \text{Expr a} \rightarrow [\text{Expr a}] \rightarrow \text{Expr a} 
\]
The composition operator takes two expressions and forms a new expression representing the composition of the two just as the normal composition (.). The application operator takes an expression (hopefully representing a function) and an expression list and forms the application of the first expression to the list of arguments. Neither of these operators do any typechecking of their arguments, leaving the responsibility of generating typecorrect programs to the programmer using the combinators.

The code generated for mutual recursive datatypes is often a list a similar functions generated in parallel and to simplify this we also provide (-.-) and (-@-) which are vectorized versions of (-.) and (-@) in the same sense as normal addition is generalised to vectors. This means that for two lists of the same length the one-element version of the operator is used componentwise so that:

\[ [f_1, \ldots, f_n] \,-.-\, [g_1, \ldots, g_n] = [f_1 \,-.\, g_1, \ldots, f_n \,-.\, g_n] \]

To build function (or variable) definitions from these expressions we provide a definition operator (-=) (together with its vectorized version (-= -)) which are used in place of the ordinary equality sign with \texttt{left -= right} forming a definition given the left and right hand sides.

\[-=\,::\,\text{Expr}\,a\,\rightarrow\,\text{Expr}\,a\,\rightarrow\,\text{Def}\,a\]

### 4.4 Other combinators

To generate type definitions we have chosen to use identically the same operators to build datatype definitions as function definitions and then mark datatype definitions as such by applying the function \texttt{datadef} as in:

\[
\text{datadef}\,[(\text{q} \,\text{"Test"} \,-@\, ([\text{q} \,\text{"a"}]) \,=\, \\
\text{sumF}\,2\,(\text{q} \,\text{"One"} \,-@\, ([\text{q} \,\text{"a"}], \\
\text{q} \,\text{"Two"} \,-@\, ([\text{q} \,\text{"a"}, \text{q} \,\text{"a"}]))]]
\]

generating the code representing:

\[
data\,\text{Test}\,a\,=\,\\n\text{One}\,a\,\\n|\,\text{Two}\,a\,a\]
\]

After being marked by \texttt{datadef} a list of function declarations will be interpreted as a list of datatype definitions. In the same way the function \texttt{typedef} markes definitions as type synonym declarations.

We also supply a number of functions which are combinations of simple building blocks and the application operator to use as a shorthand notation for functions that are almost always applied to all their arguments immediately. A simple example is:

\[
\text{quotef}\,::\,a\,\rightarrow\,([\text{Expr}\,a])\,\rightarrow\,\text{Expr}\,a\,\\n\text{quotef}\,\text{str}\,\text{list} =\,\text{q}\,\text{str}\,-@\,\text{list}
\]

5 System

As there is currently no (typed) language available that can handle polytypic functions we have, loosely based on Hollum, made a system that generates (a representation of) the Haskell code defining a number of polytypic functions given a type declaration.

5.1 Overall structure

We have taken advantage of the fact that there already are compilers which can handle both the parsing of program text to a datatype representing the definitions and the transformation of programs (as objects of this type) to executable code, so we will only deal with getting from a parsed program to a new parsed program with the declarations of the necessary generalised functions added. More specifically the system is based on nhc [14] but the part that depends on the specific compiler has been kept small by, as the first and last step, transforming input to, and output from, our internal representations.

The generalised functions are generated in three phases:

- The parsed program is scanned for type declarations and these are transformed to functors.
- The generalised function definitions (internally represented as equalities between expressions) are built from the structure of the functors. (Some intermediate functions are also defined to make the use and definition of the generalised functions easier.)
- Finally the functions built are transformed from the internal representation to the datatype of parsed programs in the compiler, and appended to the original program. This phase also cleans up the code a bit by doing some purely algebraic optimizations of the expressions (such as removing unnecessary \( \_id \)'s)

To make testing easier the system can also show the program text in the last step.

5.2 Constructing a functor for a datatype

The first phase of the function generation converts definitions to functors in three steps; it takes a list of declarations from after the parser, extracts the datatype definitions, groups them into lists of mutually recursive type definitions\(^1\) and converts these (with some restrictions) to functors.

---

\(^1\) A group of type definitions is mutually recursive if all definitions, directly or indirectly, refer to each other.
5.2.1 Representation of types
A type definition in Haskell has the structure

\[ T \, v_1 \ldots v_n = \sum_{i=1}^{m} (C_i \times \prod_{j=1}^{k_i} a_{i,j}) \]

where on the left side \( T \) is the name of the type, the \( v_i \) are type variables and on the right sides the \( C_i \) are type constructors and the \( a_{i,j} \) are type expressions.

We store this information in the following structure:

\[ -- ( (typename, [type variables]),
\quad [(constructor name, [arguments])] ) \]

```haskell
type Data a = ( (a,[a]), [(a,Typ a)] )
```

Here a type expression can be either a type name with type expressions as arguments, a type variable or a type tuple:

```haskell
data Typ a =
  TypCons  a [Typ a]
| TypVar   a
| TypTuple [Typ a]
```

The result type from the parser used must include at least the information needed to build this structure.

The first step in the conversion from datatype definitions to functors takes the parsed data into a list of `Data`, throwing away everything else. After this step nothing remains of the dependence on the datatype of the parsed result.

5.2.2 Mutually recursive datatypes
In the second step we sort the type definitions into mutually recursive groups, each of which will later become a mutually recursive functor list. We do this by seeing the list of type definitions as a directed graph, where each defined type name is a node that is connected to all the type names referenced on the right hand side of its definition. With this view finding the mutual recursive groups is the same as finding the strongly connected components\(^1\) of this digraph. These can be found by standard graph searching\(^2\). Every directly recursive type will be treated as a group of mutually recursive types with just one element.

---

1. A strongly connected component (s.c.c.) of a digraph is a subgraph in which all nodes are connected to all other nodes, directly or indirectly.
2. For each node we find the intersection of the set of all nodes reachable from it, and the set of all nodes that can reach it. This intersection is the set of all elements in the s.c.c. to which this node belongs.
5.2.3 Functorize

In the third step every type definition gets its top level list of constructors replaced by a Sum. The elements in each constructors argument list are transformed and collected into a Prod. The transformation of these elements takes a description of a type expression to a functor, \( \text{trans} :: \text{Typ} \ a \rightarrow \text{Func} \ a \), where

```haskell
data Func a =
    Prod   [Func a]  -- direct product of functors
    | Sum    [Func a]  -- sum of functors
    | Comp   [Func a]  -- composition of a constructor
        |   -- with a list of functors
    | Par    Int Int      -- type parameter, first the position
        |   -- number in the Func list
        |   -- then the local argument number
    | Rec    Int          -- recursive parameter
```

As the structure of the type expression is preserved in this process it is natural to define this transformation by means of a catamorphism on the type \( \text{Typ} \ a \). This catamorphism replaces type variables by their positions on the left hand side of the type definition (\( \text{var2par} \)), tuples by \( \text{Prod} \)s and occurrences of any of the mutually recursive type names to \( \text{Rec} \) provided that all the arguments are type variables, and in the right order (\( \text{comp2rec} \)).

```haskell
comp2rec :: a -> [Func a] -> Func a
var2par :: a             -> Func a
Prod     :: [Func a]      -> Func a
cata_Typ :: (a -> [b] -> b) -> (a -> b) -> ([b] -> b) ->
            Typ a -> b
trans   :: Typ a         -> Func a
trans = cata_Typ comp2rec var2par Prod
```

If some recursive reference is not identical to any left hand side, or if a function type is encountered \( \text{trans} \) will report an error and functorize will fail.

5.3 Implementing the combinators

We have chosen to represent a program as a list of definitions where each definition is marked as being either a datatype definition or a function definition but otherwise identical in structure. We represent definitions simply by a pair of a left and a right hand side expression.

5.3.1 Types for expressions

An expression has a very simple structure, it is either a primitive function or constant or an application of one expression to a list of expressions\(^1\).

```haskell
data Expr a = EApp (Expr a) [Expr a]
    | EPrim (PrimExpr a)
```

\(^1\) Compared with \( \lambda \)-calculus we lack the abstraction case, but with the primitive functions supplied we can write all the functions we need.
Here \texttt{PrimExpr} contains the quote case, and the representation of a number of useful functions. It would have been sufficient to use the quote case for everything, but having special cases for different functions makes it easy to do simplifications of the generated expressions in a separate phase:

\begin{verbatim}
data PrimExpr a = PEQuote a
    | PEprod Int     | PEProd Int
    | PEsum Int      | PESum Int
    | PEid | PEconst ...
\end{verbatim}

The \texttt{Int} argument to some of these constructors is the index on these functions. As an example the expression \texttt{EPrim (PEprod 3)} represents the function \texttt{prod3}.

5.3.2 Basic building blocks

To be able to make changes to these types without having to change the whole system we have defined a number of very simple functions which correspond to the different cases of the type definitions:

\begin{verbatim}
q :: a -> Expr a
q = EPrim . PEQuote
prodc :: Int -> Expr a
prodc = EPrim . PEprod
...
idc :: Expr a
idc = EPrim PEid
...
\end{verbatim}

5.3.3 Binary combinators

With the chosen type for expressions the definition of the application and composition operators is very simple:

\begin{verbatim}
(-@) :: Expr a -> [Expr a] -> Expr a
f -@ l = EApp f l
(-.) :: Expr a -> Expr a -> Expr a
f -. g = dot -@ [f,g]
    where dot = EPrim PEdot
\end{verbatim}

The definition operator \texttt{(-=)} just pairs the left and right arguments and marks this as a function definition as default.

5.3.4 Other combinators

The functions \texttt{datadef} and \texttt{typedef} change the marks on a list of definitions to make them datadefinitions and typedefinitions respectively.

5.4 Function generators

We provide functions generating the functions defined in section 3 (object and arrow, in and out, cata, ana, hylo, map, flatten, zip, parthylo and prop) for all datatypes for which we can construct a functor. We also provide functions generat-
ing the functions needed for unification (unify, match and datatypes with variables added, see section 6.5) but only for directly recursive types. All the generating functions take a description of a functor as first argument and can be mapped over the list of functor descriptions that is generated by the functorize step.

5.5 Simplification

The simplification function simp is applied to both the left and the right hand side of all function definitions. It is written as a catamorphism on the type Expr:

\[
simp :: \text{Expr } a \rightarrow \text{Expr } a
\]

\[
simp = \text{cata} \_\text{Expr} \ (\text{simpapp} \ . \ \text{simpprim})
\]

where

\[
\text{cata} \_\text{Expr} :: (b \rightarrow [b] \rightarrow b) \rightarrow (\text{PrimExpr } a \rightarrow b) \rightarrow \text{Expr } a \rightarrow b
\]

\[
\text{simpapp} :: \text{Expr } a \rightarrow [\text{Expr } a] \rightarrow \text{Expr } a
\]

\[
\text{simpprim} :: \text{PrimExpr } a \rightarrow \text{PrimExpr } a
\]

The function simpprim simplifies the indexed functions for small indices by replacing \(\text{prod}_1\) and \(\text{sum}_1\) with \(\text{id}\), \(\text{uncurry}_0\) with \(\text{const}\) and a number of other cases like these. Everything else is left unchanged.

\[
\text{simpprim} \ (\text{PEProd}_1) = \text{PEid}
\]

\[
\text{simpprim} \ (\text{PEsum}_1) = \text{PEid}
\]

\[
\ldots
\]

\[
\text{simpprim} \ (\text{PEuncurry}_0) = \text{EPrim PEconst}
\]

\[
\ldots
\]

\[
\text{simpprim} \ p = p
\]

The function simpapp simplifies applications with four rules:

\[
id \ . \ f \ = \ f \quad f \ . \ id \ = \ f
\]

\[
(f \ . \ g) \ x \ = \ f \ (g \ x) \quad \text{id} \ x \ = \ x
\]

This can easily be extended to handle more complicated cases but already now it makes the generated code much more readable in some cases and also a bit more efficient.

After these simplifications the code is either transformed to the datatype representing programs in the compiler, or printed as text. Both of these transformations are written as catamorphisms on the type Expr.
6 Unification

In this section we will describe unification (closely following Fokkinga [3]), a specific implementation of a unification algorithm using lazy arrays, and the generalisation of this algorithm to a polytypic unification algorithm.

6.1 Introduction to unification

Unification is, informally, the process of making two given expressions containing variables equal by substituting expressions for the variables. For example consider unifying \( f(x, f(a, b)) \) with \( f(g(y, a), y) \) where \( x, y \) are variables and \( a, b \) are constants. As both expressions are of the form \( f(\cdot, \cdot) \) we only need to unify \( x \) with \( g(y, a) \) and, with the same substitution, \( f(a, b) \) with \( y \). These two pairs can be trivially unified with the substitution \( \sigma = \{ x \rightarrow g(y, a), y \rightarrow f(a, b) \} \). Thus the original pair is unified by \( \sigma \cdot \sigma = \sigma^2 \) (we need to apply the substitution twice as \( y \) occurs in the substitution from \( x \)) to form the unified expression \( f(g(f(a, b), a), f(a, b)) \).

The unification fails if we ever have to unify two different constructors or constants (which we will treat as nullary constructors) or if we have to assign two different (that is, not unifiable) expressions to the same variable.

If we try to unify \( x \) with \( f(x) \) we will get \( \sigma = \{ x \rightarrow f(x) \} \) which does not by any finite number of iterations make the two expressions equal, but whose fixpoint can be seen as an infinite substitution that actually makes the expressions equal. In most applications one does not consider infinite substitutions but by allowing them in the result from the unification algorithm we can still choose if it should be allowed or not thus making the program more general.

6.2 Definitions

To make the notation more precise we will call the expressions that we unify terms. A term is recursively defined as either a numbered variable or an expression consisting of a constructor followed by a list of terms.

A substitution is a function from variables to terms, but we will also use it on terms by mapping the function to all variables in the term. Note that after one application of a substitution the resulting expression may still contain variables from the substitution.

A unifier of a pair of terms is a substitution that makes the two terms equal. A unifier of a list of such pairs is a substitution that unifies all of the pairs.
A substitution \( s \) is at least as general as \( S \) iff \( S = r \cdot s \) where \( r \) is a substitution. With this order the identity substitution is at least as general as all other substitutions.

The problem of unification can now be specified as the task of finding the most general unifier of a list of pairs of terms.

### 6.3 Outline of a unification algorithm

We want a function that given a lists of pairs of expressions finds the most general substitution or, if some pair is not unifiable, reports an error. To do this we can look at one pair at a time collecting assignments for the variables as we go through the list always checking that every new assignment conforms with the old ones.

To unify a pair of terms we can have a number of different cases depending on the form of the pair:

1. \((\text{Exp} \ a, \text{Exp} \ b)\): To unify two expressions we have first check that their top level constructors are identical and then that all their arguments are pairwise unifiable by a recursive call to unify.

2. \((\text{Var} \ i, \text{Var} \ i)\): A variable is trivially unifiable with itself without any new associations.

3. \((\text{Var} \ i, \text{term})\): To unify a variable with any term we have to include the association of \( i \) with the term, in the substitution. If there is already an association for this variable the old and the new terms must be unified which can be done with a recursive call to unify.

4. \((\text{term}, \text{Var} \ i)\): This case is handled by the previous case by just swapping the elements of the pair as unification is symmetric.

This description of the algorithm does not depend on the datatype of the expressions which makes it a perfect candidate for a polytypic algorithm. Case 2, 3 and 4 do not directly refer to the expressions so the only part that necessarily differs between unification programs for different types is case 1, the matching of two expressions.

### 6.4 Unification with lazyArray

One important choice that has to be made when implementing the unification algorithm is how to represent the substitutions. We know that when an association has been added to the substitution it will never be changed but probably looked up a number of times. In our algorithm we will also need to do lookups before the whole substitution is determined. This can all be implemented in an efficient way by using a lazy array, lazier than the standard Haskell Array construct that evaluates all indi-
Unification

ces to check that they are nonequal and within the bounds. We have therefore cho-

This version of the unification algorithm is based on the one occurring in [8].

1: unifyT :: (Eq b, Enum a, Ix a) =>
2:    (a,a) -> [(Term a b,Term a b)] -> Array a [Term a b]
3: unifyT r q = amap (map snd) a
4:   where
5:    a = lazyArray r (unify 1 q)
6:    unify :: Int -> [(Term a b, Term a b)] ->
7:       [Assoc a (Int,Term a b)]
8:    unify u [] = []   -- the empty list is trivially unified
9:    unify u ((Exp a,Exp b):q) = unify u ((match (a,b))++q)
10:   unify u ((Var n,Var m):q) | m == n = unify u q
11:   unify u ((Var m,t):q) =
12:       (m := (u,t)): 
13:          case head (a!m) of
14:            (u’,t’) | u == u’ -> unify (u+1) q
15:                | otherwise -> unify u ((t’,t):q)
16:   unify u ((t,v):q) = unify u ((v,t):q)
17:   match p = case matchD p of
18:     No -> error "can’t match expressions"
19:   Yes q -> q

The algorithm takes two arguments; r is a range of the form \((\min,\max)\) that con-

The output is an array with range \(r\) and with lists of terms as elements. If a certain
variable is free in \(q\), the corresponding list in the resulting array will be empty, but other-ise the first element of this list will be the term the variable is set equal to.

The internal function \texttt{unify} produces a list of variable associations that are lazily
inserted into an array by \texttt{lazyArray} on line 5. This means that when the assign-
ment for a variable in \(a\) is asked for, for example by the array indexing \(a!m\) on
line 13, \texttt{lazyArray} will search through its list of assignments until it finds one for
the required variable \texttt{and}, at the same time, when passing the other assignments on
the way, it will insert them too into the array. \texttt{unify} is the main unification algo-

In the first case (line 9) the function match takes care of checking the constructors and, if they are equal, zips the arguments to a list but otherwise reports an error. As all these pairs of subexpressions also have to be unified, unify is called recursively with the new pairs concatenated to (the beginning of) the list q.

The second case where two equal variables are matched just calls unify with the rest of the list.

In the third case, where a variable is matched against a term (line 11), we must check if there already is an association for that variable in a. This is dangerous since if no association has yet been made the program would get stuck waiting for itself. To prevent this from happening we first emit this association paired with a unique number u to the resulting list (line 12) and then check to see what the first association for this variable is (line 13). If the unique numbers are equal the looked up association is the one we just emitted and thus it is the first association for this variable so all is well and we can go on to unify the rest of the list (line 14). If the numbers are not equal we have an earlier association for the same variable so we have to check that the old and the new associated terms can be unified by calling unify with this pair prepended to the list.

The resulting array a is finally stripped of the internally used numbers with the amap on line 3.

As an example of the use of this algorithm we can take the first pair of terms from the introduction in section 6.1:

\[ p = ( \text{app } 'f' [x, \text{app } 'f' [a,b]], \text{app } 'f' [\text{app } 'g' [y,a],x] ) \]

where \text{app } x \ l = \text{Exp } (x,l)

\[ a = \text{app } 'a' [] \]
\[ b = \text{app } 'b' [] \]
\[ x = \text{Var } 1 \]
\[ y = \text{Var } 2 \]
\[ l = \text{unifyT } (1,2) [p] \]

The result is an array that satisfies the following two equalities: (where we assume the same where definitions as in the definition of p.)

\[ l!1 == [\text{app } 'g' [y,a]] \]
\[ l!2 == [\text{app } 'f' [a,b]] \]

### 6.5 Polytypic unification

The polytypic unification algorithm for a datatype D uses as terms elements of type VD v which is the type D with variables of type v added:

\[
\text{data VD } v \ a = \text{VDVar } v \mid \text{VDExp } (F_D (\text{VD } v \ a) \ a)
\]
This means that a value of the type $VD$ is either a variable, or an expression which is almost of the type $D$. Everything in $D$ is same except that instead of recursive referrals to $D$ itself we insert references to $VD$.

In the way we have written the lazy unification algorithm almost all type dependence is already abstracted out. When we change from the type $Term$ to $VD$ we get $VDExp$ instead of $Exp$ and $VDVar$ instead of $Var$ in the pattern matching of the four unification cases. To get rid of this dependence too we can use $out_{VD}$ on the input to remove the constructors and use $in_{VD}$ on the output to get back to the correct type. What is left after this is just the three functions $in_{VD}$, $out_{VD}$ and $matchD$ and these can be supplied as arguments to an intermediate function $unifyI$. This function is completely independent of $D$ and can therefore be defined once and for all in a prelude and need not be generated by the system. The differences between $unifyI$ and the lazy array unification algorithm from section 6.4 are marked by italics below:

```haskell
unifyI matchD inVD outVD r q = amap (map (inVD.snd)) a
  where
    a = lazyArray r (unify 1 (outlist q))
    (= these lines are the same except that
    Var becomes $In_{21}$ and Exp becomes $In_{22}$ -)
    match p = case matchD p of
       No -> error "can’t match expressions"
       Yes q -> outlist q
    outlist = map (prod2 outVD outVD)
```

With $unifyI$ defined the definition of $unify$ is trivial.

```haskell
unifyD = unifyI matchD inVD outVD
```

The function $match$ takes care of most of case 1 in the unification algorithm. First, by using $zip_{FD}$ it checks that the constructors in the top level of the two expressions are equal. After the zip the expression can contain pairs of constants which all must be equal if the expressions are to be unifiable. This is checked by first flattening the expression using $f_{FD}i$ (for all $i$) and then mapping $==$ over the resulting lists. If any of these checks fail, $match$ returns $No$, but if all succeeds it returns $Yes q$ where $q$ is the list of pairs of subexpressions which need to be unified.

```haskell
matchD :: (Eq a_1, ..., Eq a_n) =>
  (F_D b, F_D b) -> 1+ [(b,b)]
matchD = partfun pred fl_{FD} 'cmp' zip_{FD} where
  pred = and_n (alleq . fl_{FD}1) ... (alleq . fl_{FD}n)
  alleq = all (uncurry (==))
  zip_{FD} :: (F_D b, F_D b) -> 1+ FD (b,b) (a,a)
  fl_{FD} :: FD (b,b) (a,a) -> [(b,b)]
```
In this report we have explained what polytypism is, we have presented a number of basic polytypic functions, and we have shown how polytypic functions can be used. We have described a system in which a number of polytypic functions can be automatically generated using a formalism rather close to normal functional programming. The generating functions take a description of a datatype and generate functions that in some way depend on this type. We have shown that by small changes of a traditional unification algorithm, we obtain a polytypic version working for all directly recursive tree like types.

The system could be a good basis for the implementation of a polytypic programming language where types are (maybe somewhat restricted) values and polytypic functions are functions taking a type as an argument. There are a number of problems with doing this as we would need new notation to express types as values, a new type system and many other things.

A quicker way of making this system more available for experimentation would be to extend a Haskell compiler with one new keyword generating to be used with the same syntax as the deriving clause after a datatype declaration. The compiler could then call our system after the parser requesting that the code, defining the polytypic functions named in the generating construct, be generated. It would then compile the generated functions together with the rest of the program. In this way the programmer could use these polytypic functions very easily.
