**ABSTRACT**

In the course of our 870 $\mu$m APEX/LABOCA follow-up of the Herschel Lensing Survey we have detected a source in AS1063 (RXC J2248.7-4431) that has no counterparts in any of the Herschel PACS/SPIRE bands, it is a Herschel “drop-out” with $S_{870}/S_{500} \geq 0.5$. The 870 $\mu$m emission is extended and centered on the brightest cluster galaxy, suggesting either a multiply imaged background source or substructure in the Sunyaev-Zel’dovich increment due to inhomogeneities in the hot cluster gas of this merging cluster. We discuss both interpretations with emphasis on the putative lensed source. Based on the observed properties and on our lens model we find that this source may be the first submillimeter galaxy (SMG) with a moderate far-infrared (FIR) luminosity ($\approx 10^{12} L_\odot$) detected so far at $z > 4$. In deep HST observations we identified a multiply imaged $z \approx 6$ source and measured its spectroscopic redshift to be $z = 6.107$ with VLT/FORS. This source may be associated with the putative SMG, but it is most likely offset spatially by 10–30 kpc and they may be interacting galaxies. With a FIR luminosity in the range $[5–15] \times 10^{11} L_\odot$ corresponding to a star formation rate in the range $[80–260] M_\odot$ yr$^{-1}$, this SMG would be more representative of the $z > 4$ dusty galaxies than the extreme starbursts detected so far. With a total magnification of $\approx 25$ it would open a unique window to the normal dusty galaxies at the end of the epoch of reionization.

**Key words.** galaxies: high-redshift – galaxies: star formation – galaxies: evolution – submillimeter: galaxies

1. **Introduction**

Estimating the contribution of dust-obscured star formation in the early Universe is essential to constrain the models of galaxy evolution and has been a growing field of research since the late 1990s (e.g., Blain et al. 2002). Owing to the negative K-correction, distant dusty galaxies (also known as submillimeter galaxies, SMGs) were efficiently detected in submillimeter (submm) surveys and their redshift distribution was found to peak at $z \approx 2–3$ (Chapman et al. 2005).

With the advent of the new generation of submm instruments the hunt for the highest-redshift SMGs progressed at a rapid pace in recent years. The first SMG beyond $z = 5$ was discovered by Capak et al. (2011) with JCMT/AzTEC. Based on a Herschel detection and a 30 m/EMIR follow-up, Combes et al. (2012) discovered an interacting system of bright SMGs at $z = 5.243$. At the same time, Walter et al. (2012) used IRAM instruments and found that an SMG known for years in the Hubble deep field is actually a system of galaxies lying at $z = 5.2$. Following-up on SPT bolometer observations, Vieira et al. (2013), and Weiß et al. (2013) measured the spectroscopic redshifts of 23 new SMGs...
with ALMA. Of these, two are at $z > 5$. In parallel, Riechers et al. (2013) observed red SMGs based on Herschel colors with CARMA and discovered the highest-redshift SMG at $z = 6.34$.

In terms of luminosity, however, all SMGs detected so far beyond $z > 4$ are ultraluminous infrared galaxies (ULIRGs) with $L_{\text{FIR}} > 10^{12} L_{\odot}$ or even hyperluminous infrared galaxies (HyLIRGs) with $L_{\text{FIR}} > 10^{13} L_{\odot}$, implying star formation rates $SFRs \geq 10^3 M_{\odot} \text{yr}^{-1}$. As confirmed by recent ALMA number counts (Karim et al. 2013; Hatsukade et al. 2013), these extreme starbursts are not representative of the average population of dusty star-forming galaxies at $z > 4$, and the luminous infrared galaxies (LIRGs) with $L_{\text{FIR}} \sim 10^{11} L_{\odot}$ that should represent the majority are yet to be discovered. The lensing power provided by massive galaxy clusters is widely used to detect distant galaxies (e.g., Smail et al. 1997). However, the recent discovery of substructures in the Sunyaev-Zel’dovich (SZ) increment of interacting clusters (Korngut et al. 2011; Mroczkowski et al. 2012) may complicate the interpretation of submm observations. We report here the discovery of a good candidate for a normal star forming-galaxy at $z = 6.1$ lensed by the cluster AS1063 (RXCJ2248.7-4431) and discuss the possibility that this source may instead correspond to substructures in the SZ effect. We adopt the ACDM concordance cosmology: $H_0 = 71 \text{ km s}^{-1} \text{Mpc}^{-1}$, $\Omega_M = 0.27$ and $\Omega_{\Lambda} = 0.73$.

2. Observations and data reduction

Herschel observations of AS1063 at 70, 100, 160, 250, 350, and 500 $\mu$m were obtained as part of the Herschel Lensing Survey (program IDs: KDOT_eegami_1, OT2_trawle_3) as described by Egami et al. (2010) and Rawle et al. (2010). The full widths at half maximum (FWHM) of the beams are 5.2′′, 7.7′′, 11.3′′, 18.1′′, 24.9, and 36.6′′, respectively.

Observations of AS1063 at 870 $\mu$m with the Large APEX Bolometer Camera (LABOCA, Siringo et al. 2009) were obtained in the frame of the LABOCA Lensing Survey, a large program coordinated by ESO and the MPI (E187A0437A, M-087.F-0005-2011). The observations were carried out in April and May 2012 in excellent weather conditions with an average precipitable water vapor (PWV) of 0.5 mm. The spiral mapping pattern was chosen to cover a circular area of ~8′ in diameter centered on the clusters. Absolute flux calibration was achieved through observations of Mars, Uranus, and Neptune as well as secondary calibrators and was found to be accurate to within ~10% (rms). The atmospheric attenuation was determined via skylights about every 2 h and also from independent data from the APEX radiometer which measures the line-of-sight water vapor column every minute (see Siringo et al. 2009, for a more detailed description). Pointing was checked on the nearby quasars and was found to be stable within 3″ (rms). The data were reduced using the bolometer array data analysis software (BoA Schuller 2012). The effective resolution of the maps is 24.3″. The pixel noise rms at the center of the map is 1.1 mJy beam$^{-1}$.

3. Results

The LABOCA map shows a source at the center of cluster AS1063 (Fig. 1) that is extended at the resolution of LABOCA (beam FWHM = 24.3″) and centered on the brightest cluster galaxy (BCG). Its northeastern part has no counterparts in any of the Herschel bands or in the 24 $\mu$m MIPS band; it is a very red Herschel drop-out. It peaks at 7.6 ± 1.1 mJy and its 3-σ upper limit at 500 $\mu$m is 13 mJy, implying a flux ratio $S_{500}/S_{24} \geq 0.5$.

Although the BCG is not detected with Herschel (Rawle et al. 2012), the southwestern part of the 870 $\mu$m source is partly blended with the emission from two lower-redshift sources with spectroscopic redshifts $z = 0.6$ and 0.3 (Walth et al., in prep.). To extract the source properties in this crowded field we applied a multiwavelength simultaneous fit of the maps assuming a modified black-body spectral energy distribution (SED) shape (following Blain et al. 2003, with $\alpha = 2.9$ and $\beta = 1.5$) for all the sources. There are two free parameters per source, corresponding to the FIR luminosity and the wavelength of the SED peak (determined by the dust temperature, $T_d$ and the redshift, $z$). In a first iteration we ran the procedure with the two low-$z$ sources only. The residuals are shown with green contours in Fig. 2; they represent the 870 $\mu$m foreground-deblended emission. The morphology and the distribution of this emission with respect to the critical lines, with two peaks on each side of the BCG – one to the northeast at 7.6 mJy and the other to the southwest at 5.3 mJy – suggest either a multiply imaged background source or substructures in the SZ increment. We discuss the two interpretations in turn in the following section.

4. Discussion

4.1. Photometry of a putative lensed source

In a second iteration we ran the photometry procedure again to simultaneously fit two sources at the positions of the 870 $\mu$m peaks in addition to the two low-$z$ sources. We assumed that the two 870 $\mu$m sources are the images of a single lensed source, which implies a unique peak wavelength (same redshift and dust temperature) and a total of seven free parameters. The $\chi^2$ value gives us an indication of the quality of the fit, it is plotted against the redshift and the dust temperature of the lensed source in Fig. 3 with contours indicating the confidence levels. At a given dust temperature, the 870 $\mu$m flux and the Herschel upper limits impose a lower limit to the redshift. Thus, if we assume $T_d > 20$ K, as observed in most SMGs including those with the lowest luminosities (see, e.g. Symeonidis et al. 2013; Magnelli et al. 2012; or Swinbank et al. 2010) the source must be at $z \geq 2$. If $T_d = 30$ K (mean value for $L_{\text{FIR}} \sim 10^{11.5} L_{\odot}$ according to the same references), the redshift must be $\geq 4$. In addition, if we assumed $z < 7$, the observed (i.e., uncorrected for lensing) FIR luminosities of the two peaks must be $< 10^{13} L_{\odot}$ (Fig. 3).

4.2. Lens and source models

Based on the identification of 13 multiple-image systems, five of which have a spectroscopic redshift and the others have a reliable photometric redshift, we built a lens model of the cluster (Richard et al., in prep.). The critical lines computed with this model for $z = 6$ are shown in Fig. 2 as red lines.

As shown in the left panel of Fig. 2, we can reproduce the two 870 $\mu$m peaks by assuming a single source modeled by a circular Gaussian of FWHM = 2 kpc at $z = 6$. Four images of the source, labeled L1, L2, L3, and L4, are actually formed in a classical quad configuration; their magnifications are 10.8, 3.7, 7.1, and 3.1, respectively, for a total magnification $\mu = 24.7$

1 The lowest-luminosity SMG detected so far at $z > 4$ has $L_{\text{FIR}} = 1.3 \times 10^{12} L_{\odot}$ and is located at $z = 4.04$ (Knudsen et al. 2010).
Fig. 1. 105′′ × 78′′ thumbnails showing the central region of the cluster AS1063 at 3.6, 24, 70, 100, 160, 250, 350, 500, and 870 µm (from left to right and from top to bottom). The contours correspond to the 870 µm emission detected with LABOCA at 3, 4, 5 and 6-σ (σ = 1.1 mJy). The Herschel drop-out source can be seen around the BCG (marked by the green cross) at the center of the 870 µm map. The arrows in the 100 µm map point at two low-z sources (z = 0.3 and 0.6), whose 870 µm emission is blended with the southwestern part of the high-z source.

Fig. 2. Left: residuals of the 870 µm emission after subtracting the two low-z sources. The cyan contours represent the z = 6 source model lensed by the cluster and observed at the resolution of LABOCA. The four images formed are labeled L1, L2, L3, and L4. The contour levels are at 0.25, 0.5 and 0.75 × S_{L1}, where S_{L1} is the peak flux of the L1 image. The critical lines for z = 6 are overlaid in red. Right: HST color image of the cluster center of AS1063 assembled from images in the filters F606W (blue), F775W (green) and F125W (red). The white squares show the positions of the 4 images of a z = 6.1 background source. The thumbnails at the right are 3′′ × 3′′ zooms into these 4 images. The green contours show the 870 µm emission at 2.6, 3.9, 5.2, and 6.5 mJy (RMS = 1.1 mJy). The dotted green circle represents the LABOCA beam (FWHM = 24.3′′).
The two 870 µm peaks shown in Fig. 2 and the two low-z sources (at z = 0.6 and 0.3) shown in Fig. 1 are fitted simultaneously at all wavelengths from 100 to 870 µm assuming a modified black-body SED for each source (7 free parameters). The white contours show the 1σ, 2σ, 3σ, and 4σ confidence levels. Middle and right panels: best-fit FIR luminosity in log without any lensing correction in the z-Tz plane for the two 870 µm peaks. The white contours are spaced by 0.5 dex. The χ^2 3σ confidence level is overplotted in red.

The images L3 and L4 are ~3× fainter than L1 and are therefore at ~2σ, which is consistent with no detection. To obtain an L1-image brighter than the others it needs to be aligned with a galaxy of the cluster such that it undergoes an additional magnification. In this model the L1-image is formed close to two galaxies of the cluster. The differences between the model and the data are ≤3σ. Because the angular distance between the two peaks (L1 and L2) decreases with decreasing redshift, our lens model puts a strong constraint on the redshift, which must be ≥4 if we assume a single source. We note that it is possible that the southern source arises from lensing of a second background galaxy, but this would imply multiple sources with similar very red SEDs.

Hence, according to our lens-source model and to the photometry, the luminosity of the putative lensed source corrected for lensing is most likely <10^{12} L⊙, which is an order of magnitude lower than that of SMGs detected at z > 4 so far. For example, if we assume T⊙ = 30 K and z = 6, the observed luminosity of the northern peak is L_{FIR} = 5 × 10^{12} L⊙ (middle panel of Fig. 3), with μ_{L1} = 10 this implies an intrinsic luminosity L_{FIR} ∼ 5 × 10^{11} L⊙.

4.3. A plausible HST counterpart at z = 6.107

In the HST images and catalogs provided by the CLASH project we identified four objects (named 6.1, 6.2, 6.3 and 6.4, in Fig. 2 as in Richard et al., in prep.), which might be the four images of a high-z source. Indeed, fitting various SED templates to the HST photometry, we derived a redshift z = 6.3 ± 0.3 (Fig. 4) and the image positions were accurately reproduced by our lens model for a source at z = 6. To confirm the redshift we recently obtained VLT/FORS spectroscopy of the 6.2, 6.3, and 6.4 images. The Ly-α line is clearly detected at z = 6.107 (Fig. 4)\(^2\). The magnifications are μ_{6.1} = 17.1, μ_{6.2} = 6.7, μ_{6.3} = 5.9, and μ_{6.4} = 2.5.

The image 6.1 of this HST source benefits from a boost by two galaxies of the cluster as in Richard et al., in prep., which might be the four images of a high-z source. Indeed, fitting various SED templates to the HST photometry, we derived a redshift z = 6.3 ± 0.3 (Fig. 4) and the image positions were accurately reproduced by our lens model for a source at z = 6. To confirm the redshift we recently obtained VLT/FORS spectroscopy of the 6.2, 6.3, and 6.4 images. The Ly-α line is clearly detected at z = 6.107 (Fig. 4)\(^2\). The magnifications are μ_{6.1} = 17.1, μ_{6.2} = 6.7, μ_{6.3} = 5.9, and μ_{6.4} = 2.5.

The SFR of the HST source estimated from the UV continuum and from the Ly-α line and corrected for lensing are

\(^2\) Recently Bradley et al. (2013) mentioned a quintuple system in this cluster, but they listed only three of our identified images (6.1, 6.3, and 6.4). After the submission of our letter two other articles appeared online (Monna et al. 2013; Balesstra et al. 2013) that describe this system in more detail and provide a similar spectroscopic redshift. We confirm the fifth image identified by these authors and show it in Fig. 2 as 6.5.
5. Conclusion

With APEX/LABOCA we have detected an extended 870 μm source aligned with the center of the cluster AS1063. The source is not detected at shorter FIR/submm wavelengths. We found two possible interpretations of this peculiar source: it may be the dusty component of an HST-detected strongly lensed galaxy at \(z = 6.1\) or substructures in the SZ effect. The current observations do not allow us to conclude in favor of one of the two interpretations.

There are two routes to decide between the different origins of the features we discovered: submm observations with ALMA are expected to allow us to resolve the four images of the high-\(z\) source, while lower-frequency observations (150 GHz) are required to measure the decrement of the SZ substructures.

Acknowledgements. We thank the referee for insightful and constructive comments. We are very grateful to the APEX staff for their great help with the observations and their warm welcome at the Sevostopol base. We gratefully acknowledge the ESO director for the VLT/FORS program DDT 291.A-5027. We kindly acknowledge Etienne Pointecouteau for providing us with the Planck data and for useful discussions.
