

How do sustainability standards consider biodiversity?

Oskar Englund* and Göran Berndes

Sustainability certification schemes and standards are meant to prevent a range of unacceptable socioeconomic and environmental consequences, such as threats to biodiversity. While there is wide support for conserving biodiversity, operationalizing this support in the form of guiding principles, criteria/indicators, and legislation is complicated. This study investigates how and to what extent 26 sustainability standards (eleven for forest management, nine for agriculture and six biofuel-related) consider biodiversity, by assessing how they seek to prevent actions that can threaten biodiversity as well as how they support actions aimed at biodiversity conservation. For this purpose, a benchmark standard was developed, meant to represent a case with very high ambitions concerning biodiversity conservation. Of the assessed standards, the biofuel-related standards demonstrated the highest level of compliance with the benchmark. On average, they complied with 72% of the benchmark's component criteria, compared to 61% for the agricultural standards and 60% for the forestry standards. Fairtrade, Sustainable Agriculture Network/Rainforest Alliance (SAN/RA), Roundtable on Sustainable Palm Oil (RSPO), and Roundtable on Responsible Soy (RTRS) were particularly stringent, while Green Gold Label S5 (GGLS5), PEOLG, Global Partnership for Good Agricultural Practices (GLOBALGAP), European Union Organic (EU Organic), National Organic Program (NOP), Green Gold Label S2 (GGLS2), and International Sustainability & Carbon Certification (ISCC) were particularly unstringent. All eleven forestry standards, six of the nine agricultural standards, and all six biofuel-related standards addressed ecosystem conversion, ranging from requiring that high conservation value areas be identified and preserved to requiring full protection. Finally, key barriers to, and challenges for, certification schemes are discussed and recommendations are made for further development of sustainability standards.

INTRODUCTION

Meeting the increasing demand for biomass-based products without creating unacceptable socioeconomic and environmental consequences is a great challenge.^{1,2} Human societies already use roughly half the planet's land surface, producing biomass with a total energy content equivalent to about 20% of the

total global net primary productivity.³ Human land use has caused extensive land degradation and biodiversity loss, as well as emissions to air and water that contribute to, e.g., eutrophication, acidification, stratospheric ozone depletion, and climate change.⁴⁻⁶

A growing awareness of the possible size and land use consequences of the rapidly growing bioenergy sector has prompted demands that resources and feedstocks be put to best use and that environmental and social effects of changing production systems (positive and negative) be understood as production grows.⁷ Promotion of bioenergy offers considerable opportunities for the agricultural and forestry sectors, which can find new markets for their products and

Conflict of interest: The authors have declared no conflicts of interest for this article.

also make economic use of biomass previously considered mere waste. Further, many options exist for developing synergies among different land uses,^{8,9} as well as for shaping land use systems with less impacts on land, water and biodiversity.^{10–14} However, a given objective often conflicts with others. Thus, the development of land use often takes place in the context of trade-offs among more or less incompatible objectives, and promoting sustainable land use realistically requires balancing objectives in terms of environmental and socioeconomic factors.^{15,16}

Governance is an essential component of a sustainable energy system. Legislation and regulation as well as sustainability standards and certification schemes are required to guide deployment of bioenergy production systems. Bioenergy feedstock producers in the private sector, as well as governmental and nongovernmental organizations, have taken initiatives to develop criteria/indicators for sustainable biomass production. These can for instance be applied in legislation, such as the EU Renewable Energy Directive (EU-RED), and in sustainability certification schemes. These governance systems can help mitigate negative impacts and promote best management practices, and their use also contributes to shaping the way land is used to produce food and biomaterials.

A variety of generic sustainability certification schemes exist for agriculture and forestry, but they can also be crop-specific or relate to a specific end use of biomass, e.g., bioenergy. In addition, a number of non-operational sustainability standards exist, which are developed to guide or influence other actors involved in developing operational standards, such as certification schemes or policymakers. Such guidelines have been developed by, e.g., International Tropical Timber Organization (ITTO), for sustainable management of tropical forests; International Federation of Organic Agriculture Movements (IFOAM), for organic agriculture; and the Global Bioenergy Partnership (GBEP), for sustainable bioenergy feedstock production. Many sustainability standards exist, both mandatory and voluntary, and with varying scope. They also differ in how they prioritize different aspects of sustainability. For example, some may be very focused on the environmental performance of a production system, while others focus more on social aspects.

Studies show that there are many challenges associated with the current status of sustainability certification and standards, including the heterogeneity of systems.^{17–21} According to noncertified producers, main barriers include high administrative complexity, high costs, and small market advantages.^{22,23} In addition, stakeholders along bioenergy supply chains may need to comply with different standards to maintain

market access and to comply with legislative mandates. Consumers who try to make environmentally conscious purchasing decisions and regulatory agencies and governments involved in enforcing sustainability standards may find it difficult to manage a wide range of systems that use different criteria/indicators. Thus, the proliferation of schemes and standards has led to confusion among actors involved, market distortion and trade barriers, an increase in commodity costs, and questions about the adequacy of systems in place and how to develop systems that are effective and cost efficient.^{22,24–26} A recent study undertaken to monitor the actual implementation process of sustainability certification of bioenergy found that there is no global/common definition of how the sustainability concept should be translated into practice, i.e., how to measure sustainability and which criteria/indicators to use.²² The study called for a globally harmonized approach and establishment of a common language, including terminology, to describe sustainability and how it should be verified/documented.

Biodiversity presents a challenge for sustainability certification. While there is wide support for the objective to conserve biodiversity (e.g., the Convention on Biological Diversity has 193 parties and 168 signatures)²⁷ operationalization into guiding principles, criteria/indicators, and legislation is complicated. For example, in 2009, the EU-RED established that raw materials used for the production of biofuels and bioliquids may not be produced on land that had the status of highly biodiverse grassland in or after January 2008. At the time of writing (June 2013), the European Commission is still in the process of operationalizing elements of the biofuel sustainability criteria, including clarifying some of the requirements that need to be met with respect to the biodiversity criteria, e.g., in relation to highly biodiverse grasslands.

This article presents an assessment of how biodiversity is considered in different types of sustainability standards. First, biodiversity is defined and strategies for biodiversity conservation are discussed. Then, standards for sustainable production of biomass in agriculture and forestry are evaluated on how they consider biodiversity, i.e., how they attempt to prevent actions that can threaten biodiversity and support actions that can conserve it. It is also assessed how sustainability standards address the conversion of certain ecosystem types. A broad set of standards is included—relating to either (1) sustainable agricultural management; (2) sustainable forest management; or (3) sustainable production of biofuel feedstocks. Similarities and differences within and between the three categories are identified. Finally, key barriers to,

TABLE 1 | Definition of Biodiversity, Using Four Components

	Species Diversity	Ecosystem Diversity	Genetic Diversity	Functional Diversity

and challenges for, certification schemes are discussed and recommendations are made for further development of sustainability standards.

BACKGROUND

Biodiversity has been defined in many different ways. Often, it is considered equal to *species diversity/richness*. However, this is an oversimplification.²⁸ The Convention of Biological Diversity (CBD) and the Millennium Ecosystem Assessment (MEA) highlight the complexity of biodiversity by defining it as: ‘the variability among living organisms from all sources including, *inter alia*, terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems’.^{29,30} CBD describes biodiversity by using three principal levels: ecosystems, species, and genes; the variation within these levels is described with reference to specific concepts, e.g., at the species level, richness, abundance and function.²⁹ Here, biodiversity is defined using four components: *species diversity*, *ecosystem diversity*, *genetic diversity*, and *functional diversity* (Table 1).

Species diversity is what most people associate with the term biodiversity and also the aspect that is most commonly referred to when preservation issues are discussed.²⁸ *Ecosystem diversity* is, along with functional diversity, the most important factor when assessing the stability of an ecosystem at the landscape level.³⁰ *Genetic diversity* refers to the variation at the level of polymorphism in a population. A large genetic diversity gives a better chance to adapt to changing conditions, such as climate change. Some of the individuals in the population are in that case more likely to have allelic variants that are suited for the new conditions and will be able to pass those on to their offspring.³¹ Species that contribute to biogeochemical cycles (e.g. water-, matter-, carbon-, and nitrogen cycling) in similar ways, i.e., that have similar functional traits, are called functionally equivalent species and form functional groups.³⁶ An ecosystem with few

functional groups and/or with few functionally equivalent species in each group will be more vulnerable to environmental change. Therefore, both the number of functional groups (i.e. the number of functional traits) and the number of functionally equivalent species in each group contribute to *functional diversity*. Fewer species in general (a decline in species diversity) may result in fewer functionally equivalent species and therefore a decline in functional diversity and higher vulnerability to environmental changes.^{28,30,35}

Preservation of unmanaged areas is a common strategy for conserving biodiversity in, e.g., legislation, international agreements, and certification standards. However, what is considered ‘natural biodiversity’ is in many cases a consequence of centuries of human influence. Cropland and pastures constitute fundamental elements in many landscapes, and the composition of species and ecosystems in such landscapes has successively changed from that of earlier stages, when there was less influence from human activities.²⁹ Therefore, it is important to examine how agricultural and forest management can be shaped so as to support biodiversity conservation in *production landscapes*. Ecoagriculture research is one approach, attempting to clarify how agricultural landscapes can support a higher level of biodiversity, with neutral or even positive effects on agricultural production and livelihoods.³⁷ Landscape ecology,³⁸ countryside biogeography,³⁹ and GIS-based landscape modelling,⁴⁰ are other examples of disciplines and tools that can advance our understanding of interactions between managed and unmanaged areas, and the effects of different production systems on biodiversity.³⁷

ASSESSING BIODIVERSITY CONSIDERATIONS IN SUSTAINABILITY STANDARDS

In order to build on the collective scientific knowledge of sustainability standards in relation to biodiversity and ecosystem services, a review was made of 205 scientific articles (published 2006–2012) that were

identified based on database searches.^{a,b,c,d} A collection of 35 articles was considered relevant (Table 2). Most of these papers focused on biodiversity; no paper was found with a primary focus on ecosystem services, although in four papers it was jointly or secondarily addressed. Given that biodiversity can be defined in different ways,²⁸ it is notable that 16 of the 35 papers did not define or describe biodiversity. Of the remaining papers, four discussed species diversity, one discussed genetic diversity, and the rest of the papers discussed more than one aspect of biodiversity. Furthermore, most of the relevant studies concerned forest management (23/35), primarily in boreal and temperate forests (20/35). Two studies concerned agricultural production systems, and one single study investigated both sectors. The remaining studies primarily concerned cocoa or coffee cultivation. Two papers were particularly relevant: Marjokorpi and Salo⁶⁰ benchmarked eight standards and guidelines for sustainable forest plantation management, applicable in tropical and subtropical regions, against a reference standard based on a categorization of key concepts of biodiversity. Hennenberg et al.⁷⁰ benchmarked forest and agricultural management standards, relevant for bioenergy, against each other.

On the basis of the findings of the review, scope and methodology were developed with the ambition to produce results and insights beyond what was found in the reviewed articles. The assessment includes benchmarking a selection of sustainability standards against a benchmark standard, developed to represent a case with very high ambitions concerning biodiversity conservation, covering main agricultural and forestry related activities that influence biodiversity. This allows for comparisons within a sector-category of standards, as well as between standards categories, i.e., between different sectors.

Selection of Sustainability Standards

Four different categories of standards were considered: (1) standards for certification of sustainable forest management; (2) standards for certification of sustainable agricultural management; (3) standards for certification of sustainable production of specific crops commonly used as biofuel feedstock; (4) standards for sustainable production of unspecified biofuel feedstock. In addition, guidelines for development or implementation of standards that can be sorted under (1–4) were also considered. A total of 26 standards were selected for the assessment, including 11 forest management standards, 9 agriculture management standards, and 6 biofuel-related standards (Table 3). All selected standards include a set of principles and

criteria/indicators, or the equivalent (standards often differ in their terminology), indicating each standard's requirements for production to be considered sustainable or responsible.

Development of the Benchmark Standard

Sustainability standards should address actions that may cause biodiversity impacts as well as strategies for preventing biodiversity impacts. Agriculture and forestry systems differ concerning the extent to which associated management activities affect biodiversity, but many management practices are common to both (e.g., land clearing and preparation, planting, and harvesting). Specific conservation strategies may also be relevant in both agriculture and forestry. Therefore, actions that negatively affect biodiversity and strategies to protect biodiversity can be formulated so as to be relevant for both agriculture and forest management. Consequently, one general biodiversity-focused benchmark standard was developed for the purpose of facilitating an assessment of the extent to which both agricultural and forestry standards consider the key elements of biodiversity conservation.

Actions that *threaten* biodiversity include (1) habitat destruction and fragmentation; (2) habitat degradation and modification; (3) overexploitation (including overhunting, and overconsumption of resources necessary for wild species to survive); (4) introduction of nonnative (invasive) species; (5) pollution (including human induced changes in climate); and (6) human population growth (or rather, the corresponding potential increase in resource consumption).^{31,109,110} It should be noted that forest fragmentation is a type of degradation process. But since the reference standard includes criteria covering *actions* rather than *effects* of actions, and since it needs to be relevant for both forestry and agriculture, the division of actions as above was judged most suitable.

Conservation biology provides principles and tools for preserving and restoring biodiversity. The general principles developed by the scientific organization Society for Conservation Biology include nine *strategies* that need to be combined in order to conserve nature. These are: (1) protect species at risk of extinction; (2) designate ecological reserves; (3) lessen the human impact on natural systems; (4) restore ecosystems that have been degraded; (5) augment populations with individuals raised in cultivation or captivity; (6) control the number of individuals harvested in nature; (7) prevent establishment of nonnative species, and eliminate nonnative species that have become established; (8) understand and participate

in the policy-making process; and (9) educate others about the importance of conservation.^{109,111}

The *benchmark standard* was developed using seven *principles* based on the above described threats and strategies, under which 26 *criteria* were defined and sorted (Table 4). The criteria were intended to translate the broadly formulated principles into concrete actions applicable to both agriculture and forest management. The development of the benchmark criteria was supported by the literature review and a pre-assessment of the standards selected for assessment, in order to ensure a compatible format. This pre-assessment also ensured that all biodiversity related principles, criteria/indicators, and potential guidance for compliance in the assessed standards were covered by suitable benchmark criteria.

The selected standards were individually compared with the benchmark standard and for each benchmark criterion it was determined whether a specific standard was *compliant* or not. In addition, based on the specifics of compliance with the criteria sorted under a given principle, each standard was given a numerical value for that principle, reflecting the degree to which the standard *considers the principle* (0: principle disregarded; 1: principle considered in part; 2: principle fully considered, cf. Table 4). The overall biodiversity *stringency* of a given standard was finally obtained by summing the compliance values given for all seven principles, for that standard. Standards reaching a sum of 10 or more were classified as *Stringent*, and standards reaching a sum of six or less were classified as *Unstringent*.

Assessment of Ecosystem Conversion

Given that land conversion may induce adverse effects on biodiversity, it was investigated how the standards addressed conversion of certain types of ecosystems, namely: (1) tropical and subtropical forests; (2) temperate forests; (3) boreal forests; (4) wetlands; (5) grass-, shrub- and woodlands; and (6) degraded land. A pre-assessment was performed for the purpose of identifying how the standards address conversion of natural ecosystems, in general terms. It showed that the assessed standards address land conversion in four principal ways: *protecting* (no production allowed); *restricting* (production is allowed, provided that properties of ecosystems are not altered); *encouraging* (production on certain lands is encouraged); and *requiring a high conservation value (HCV) assessment* (*restricting* production on, or fully *protecting*, HCV land). All standards were then assessed to clarify how they address conversion of the ecosystem types given above (i.e., by either protecting, restricting, encouraging, or requiring an HCV assessment).

ASSESSMENT OUTCOME

Below, the degree of compliance with criteria, the overall *consideration* of principles, and the *stringency* of the assessed standards are presented. The results for the three categories of standards are then compared. Finally, the results of the ecosystem conversion assessment are presented.

Standards for Sustainable Forest Management

On average, the 11 assessed forestry standards comply with 60% of the relevant benchmark criteria, complying with 8 (Green Gold Label S5; GGLS5) to 19 (Naturland) of the 25 criteria (Table 5).

Benchmark criteria that were *well considered* overall by these standards (i.e., criteria where at most one of the assessed standards failed to reach compliance) include those related to (1) endangered species within the production area; (2) habitat destruction; (3) HCV areas; (4) water resources; (5) erosion; (6) soil quality; and (7) long-term sustainability.

Fewer than half of the assessed forestry standards reached compliance with criteria related to: (1) pesticide application; (2) fertilization (3) waste management; (4) recycling; (5) invasive species; (6) GMOs; (7) energy use; (8) fossil energy; (9) research; and (10) awareness.

Four principles are *poorly considered* overall by the assessed forestry standards. Only one standard fully complies with *Energy use and GHG emissions*; only two standards fully comply with *Habitat degradation and modification* and *Invasive species and GMOs*; and only three standards fully comply with *Research, awareness, and education*. Overall, the standards comply well with the principles *Endangered species*, *Habitat destruction and fragmentation*, and *Overexploitation* (Table 6).

The results indicate that Forest Stewardship Council (FSC), Sustainable Forestry Initiative (SFI), Malaysian Timber Certification System (MTCS), Naturland, and International Tropical Timber Organization and International Union for Conservation of Nature (ITTO/IUCN) are *Stringent*, from a biodiversity perspective. GGLS5 and PEOLG are *Unstringent* (Tables 5 and 6).

Standards for Sustainable Agriculture

On average, the nine assessed agricultural standards comply with 61% of the benchmark criteria, complying with 7 (Green Gold Label S2; GGLS2) to 23 (Fairtrade) of the 25 criteria (Table 7).

Benchmark criteria that were *well considered* overall by these standards (i.e., criteria where at most

TABLE 4 | Reference Standard Used for Benchmarking of Selected Standards (benchmark standard)

Principles	Criteria	Consideration levels	
		Considered	Partly Considered
1. Endangered species: Threatened and endangered species shall be preserved, within and around the production area.	1.1. Threatened and endangered species within the production area shall be identified and protected	1.1 and 1.2	1.1 only
	1.2. Threatened and endangered species around the production area shall be considered		
2. Habitat destruction and fragmentation: All parts of the production chain shall be managed in such a way that the destruction and fragmentation of natural habitats is minimized.	2.1. Habitat destruction is avoided	2.1–2.3	At least one
	2.2. Specific strategies for avoiding habitat fragmentation need to be applied		
	2.3. HCV areas need to be identified and preserved		
3. Habitat degradation and modification: All chemicals and fertilizers as well as the production techniques in the entire production chain, shall be chosen in such ways that they do not contribute to the degradation and modification of habitats around the production area or the alteration of functional diversity in and around the production area.	3.1. The use of chemicals for pest management (pesticides) is restricted, to avoid substances that can be harmful for untargeted species. A list of prohibited chemicals should be provided.	At least six of 3.1–3.7	At least four of 3.1–3.7
	3.2. Guidance for pesticide application is provided, to avoid contamination of surrounding terrestrial and aquatic ecosystems		
	3.3. Guidance for fertilization is provided, to minimize nutrient leaching to surrounding terrestrial and aquatic ecosystems		
	3.4. Buffer zones are required to protect watercourses		
	3.5. Water resources protected		
	3.6. Soil erosion prevented		
	3.7. Soil quality maintained		
	3.8. Waste management applied		
	3.9. Recycling applied		
4. Overexploitation: The production system shall be managed sustainably over time. Overharvesting of production species shall be avoided and soil fertility maintained.	4.1. Long-term sustainability considered	All relevant ¹	At least one relevant ¹
	4.2. Sustainable harvest rates identified and applied		
	4.3. Crop-rotation applied		
5. Invasive species and GMOs: Exotic species or GMOs shall not be used, in order to avoid disturbing natural ecosystems and the genetic diversity in populations of native species.	5.1. Native species preferred over exotic	5.1–3	At least one
	5.2. Measures taken to prevent introduction of invasive species		
	5.3. GMOs prohibited		
6. Energy use and GHG emissions: Net GHG emissions from biomass production shall be neutral or negative. Therefore, energy use needs to be minimized, fossil fuels avoided and the natural carbon stock maintained or enhanced.	6.1. Energy use minimized	6.1–3	At least one
	6.2. Fossil energy avoided ²		
	6.3. Carbon stock maintained or enhanced		
7. Research, awareness, and education: Improvements in biodiversity conservation are dependent on continuous research and increased environmental awareness among consumers and people living in or near sensitive ecosystems. Proper education for workers is key for successful implementation of certification criteria.	7.1. Research supported	7.1–3	At least one
	7.2. Awareness spread		
	7.3. Education to workers provided		

GHG, Greenhouse gas; GMO, Genetically modified organism; HCV, high conservation value.

¹‘4.2 Sustainable harvest rates’ relevant for forest management; ‘4.3 crop rotation’ relevant for agricultural management.

²Should not be interpreted as fossil fuels are prohibited—but that producers are encouraged to avoid them.

one of the assessed standards failed to reach compliance) include those related to (1) habitat destruction; (2) pesticide use; (3) fertilization; (4) water resources; (5) erosion; (6) soil quality; (7) waste management; (8) long-term sustainability; and (9) crop rotation.

Fewer than half of the assessed standards reached compliance with criteria related to: (1) endangered species within the production area; (2) endangered species around the production area; (3) habitat fragmentation; (4) native species; (5) invasive species; (6) energy use; (7) fossil energy; (8) carbon stock; (9) research; and (10) education.

Four principles are *poorly considered* overall by the assessed agricultural standards. No standard fully complies with *Invasive species and GMOs*, and only two standards comply fully with *Endangered species*, *Energy use*, and *GHG emissions* and *Research, awareness, and education*, respectively. Overall, the standards comply well with *Overexploitation* and *Habitat degradation and modification*, and the same can be seen for *Habitat destruction and fragmentation*, although to a lesser extent (Table 8).

The results indicate that Fairtrade, Sustainable Agriculture Network/Rainforest Alliance (SAN/RA), Naturland, and KRAV are *Stringent*, from a biodiversity perspective. Global Partnership for Good Agricultural Practices (GLOBALGAP), European Union Organic (EU Organic), National Organic Program (NOP), and GGLS2 are *Unstringent* (Tables 7 and 8).

Biofuel-Related Sustainability Standards

On average, the assessed biofuel-related standards comply with 72% of the benchmark criteria, complying with 13 (International Sustainability & Carbon

Certification; ISCC) to 21 (Roundtable on Responsible Soy; RTRS) of the 25 criteria (Table 9).

Benchmark criteria that were *well considered* overall by these standards (i.e., criteria where at most one of the assessed standards failed to reach compliance) include those related to (1) endangered species within the production area; (2) habitat destruction; (3) HCV areas; (4) pesticide use; (5) pesticide application; (6) buffer zones; (7) water resources; (8) erosion; (9) soil quality; waste management; (10) long-term sustainability; (11) invasive species; and (12) carbon stock.

Fewer than half of the assessed standards reached compliance with criteria related to: (1) native species; (2) GMOs; (3) fossil energy; (4) research; and (5) education.

Two principles are *poorly considered* overall by the assessed biofuel-related standards. No standard fully complies with *Invasive species and GMOs* or with *Research, awareness, and education*. Overall, the standards comply well with *Endangered species*, *Habitat destruction, and fragmentation*, *Habitat degradation and modification* and *Overexploitation* (Table 10).

The results indicate that Roundtable on Sustainable Palm Oil (RSPO), RTRS, Bonsucro, and Greenenergy are *Stringent*, from a biodiversity perspective. ISCC is *Unstringent* (Table 9 and 10).

Comparison of Outcomes for the Three Categories of Standards

The assessed biofuel-related standards reached the highest level of compliance, complying on average with 72% of the benchmark criteria, compared to

61% for the agricultural standards and 60% for the forestry standards. There are large variations between the standards categories regarding compliance with some benchmark criteria (Table 11, Figure 1). In some cases (e.g., guidance for fertilization), this can be explained by the differences between forest management and agricultural management. In other cases (e.g., preferred use of native species), the reason is less clear. Criteria that were *well considered* across all three standards categories include those related to (1) habitat destruction; (2) water resources; (3) soil erosion; (4) soil quality; and (5) long-term sustainability. Overall *poorly considered* criteria include those related to (1) fossil energy and (2) support for research.

Further, the forestry and biofuel-related standards are generally more stringent than the agricultural standards regarding endangered species, both within and around the production area. The same result was found for habitat fragmentation and requirements for HCV assessments. This is reasonable for forestry standards, since forests subject to some degree of management typically host natural ecosystems to a larger degree than agriculture. It was less expected that biofuel-related standards would differ from agricultural standards, since most of the assessed biofuel-related standards refer to agriculture to a higher degree than to forestry.

The agricultural and biofuel-related standards are somewhat more stringent than the forestry standards concerning the use of pesticides. This is reasonable since pesticides are more commonly used in agriculture than in forestry. In addition, since agricultural products are used for human consumption, pesticides in agriculture may be of higher concern than in forestry. Guidance for pesticide application is

more common in the biofuel-related standards than in the agricultural standards, even though several of the biofuel-related standards are not explicitly aimed at agricultural production.

All biofuel-related standards require buffer zones, while the forestry and agricultural standards are less stringent in that regard. Requirements of waste management and recycling are more common in the agricultural and biofuel-related standards than in the forestry standards. This is reasonable since agriculture is more intensive than forestry and thereby uses more material and inputs, and thus causes more waste. All but one of the biofuel-related standards, about half of the forestry standards, and only one of the agricultural standards, require measures to prevent the introduction of invasive species.

Energy use and biospheric carbon stocks are considered to a higher degree in the biofuel-related standards than in the forestry and agricultural standards. Given that GHG emissions reduction should be an important objective in land use in general, this can be considered a weakness in forestry and agricultural standards. Perhaps surprisingly, the biofuel-related standards typically do not promote renewable energy. Spreading awareness is considered to a higher degree in the agricultural and biofuel-related standards than in the forestry standards, while the opposite is the case for education and training of workers.

Habitat destruction and fragmentation and *Overexploitation* are principles *well considered* by the assessed forestry standards. *Poorly considered* principles include *Energy use and GHG* and *Research, awareness, and education* (Figure 2). *Habitat degradation and modification* and *Overexploitation* are

principles *well considered* by the assessed agricultural standards. *Poorly considered* principles include *Endangered species*, *Invasive species and GMOs*, *Energy use and GHG* and *Research, awareness, and education* (Figure 2). *Habitat destruction and fragmentation* and *Habitat degradation and modification* are principles *well considered* by the assessed biofuel-related standards. *Poorly considered* principles include *Invasive species and GMOs* and *Research, awareness, and education* (Figure 2).

Ecosystem Conversion Assessment

The ways the assessed standards address conversion of seven main ecosystem types is presented in Table 12. All of the eleven forestry standards address ecosystem conversion. For forested land, conversion is typically regulated by requiring that *HCV* areas be identified and protected. Exceptions include *Natural* (which *restricts* conversion of forested land), and *GGLS5* (which *protects* forested land from conversion into plantation forest). Among the assessed forestry

standards, only the ITTO/IUCN standard covers a nonforest ecosystem (wetlands) in its required HCV assessment—the other standards cover forest ecosystems only. In addition, few of the standards address conversion of nonforested land by other means than requiring HCV assessments: Wetlands are *protected* by SFI and Naturland, and conversion is *restricted* by FFCS and PEOLG. Conversion of grass, shrub-, and woodlands is *encouraged* by PEOLG, while Naturland *protects* such ecosystem types. The remaining forestry standards do not consider nonforest ecosystems. Thus, in some cases, it may be possible to convert highly biodiverse grasslands or wetlands into certified plantation forests.

Six of the nine agricultural standards address ecosystem conversion (exceptions: EU Organic, NOP, and GGLS2). Contrary to the forestry standards, the agricultural standards that address ecosystem conversion typically do not rely solely on HCV assessments for identifying no-go areas (exception: Fairtrade). Instead, they require that all natural vegetation remain unmanaged. Thus, in some cases (i.e., EU Organic, NOP, and GGLS2), farmers may be able to convert any ecosystem type into certified cropland, while in other cases (i.e., all the other assessed agricultural standards), farmers are basically not able to convert any type of unmanaged land into certified cropland.

All six biofuel-related standards consider ecosystem conversion. While the forestry standards rely on HCV assessments and focus primarily on forested lands, and agricultural standards either protect everything or nothing, the biofuel-related standards consider all the ecosystem types, either by requiring protection or a combination of protection and HCV assessments. RSPO, e.g., protects forested land and wetlands, requires an HCV assessment for grasslands, and encourages conversion of degraded lands. This is likely a direct effect of the sustainability requirements in EU-RED, which state that forested lands, wetlands,

and highly biodiverse grasslands are no-go areas for biofuel feedstock production, if the products are to be sold on the EU-RED market. Since all six biofuel-related standards are RED-approved, areas that are no-go according to RED are also no-go areas in these standards.

Overall, five standards encourage restoration of degraded land; three forestry standards (ATTO/ITTO, ITTO/IUCN and PEOLG) and two biofuel-related standards (RSPO and RTRS). Four standards protect degraded lands in different ways; one forest standard (Naturland) and three agricultural standards (GLOBALGAP, IFOAM, and SAN/RA). Only one of the five assessed RED-approved standards (RTRS) encourages restoration of degraded land, even though the latter measure is included in RED as an option for earning GHG emissions savings bonuses. This may be explained by the fact that it is not yet possible to earn such bonuses, due to the delay in developing a definition of ‘degraded land’.

SUMMARY AND DISCUSSION OF ASSESSMENT OUTCOME

In summary, the assessed biofuel-related standards had the highest level of compliance with the benchmark standard, complying on average with 72% of the benchmark criteria, compared to 61% for the agricultural standards and 60% for the forestry standards. Fairtrade and SAN/RA (agriculture), and RSPO and RTRS (biofuel) were the most stringent, while GGLS5 and PEOLG (forest), GLOBALGAP, EU Organic, NOP, and GGLS2 (agriculture), and ISCC (biofuel) were the least stringent.

In general, the assessed standards consider *habitat destruction*, *-fragmentation*, *-degradation*, *-modification*, and *overexploitation* well, while *invasive species and GMOs*, *research*, *awareness*, and

‘+’, benchmark criteria complied with by all the assessed standards, with one exception allowed; ‘–’, benchmark criteria complied with by less than 50% of the assessed standards; GHG, xxx; GMO, xxx.

education, and *Energy use and GHG* are poorly considered.

There are notably large differences in stringency between some standards having a similar scope. For example, IFOAM, which sets the ‘norms’ for organic agriculture, is significantly more stringent than either EU Organic or NOP. In addition, KRAV endorses EU Organic, even though KRAV classifies as *Stringent* and EU Organic as *Unstringent*. Further, the SFI standard, which is a forest industry initiative, shows similar stringency as the FSC standard, which is often regarded as more thorough in its coverage of ecological issues.⁵¹ Furthermore, the high stringency in the Fairtrade standard, and to some extent also

SAN/RA, was unexpected, as these are perceived to primarily focus on social aspects.

Some of the differences in stringency can be explained by differences concerning biophysical properties or legal contexts in countries or regions in which the standards originate or for which they are intended. For example, standards targeting production in countries that have less stringent environmental legislation and/or limited enforcement capacity—and where agriculture or forestry sectors are still expanding onto natural vegetation—likely need to be more stringent than standards developed for countries where the existing protection of remaining natural ecosystems is effective and where the land

FIGURE 1 | Percentage of benchmark criteria complied with by the three standard types, respectively.

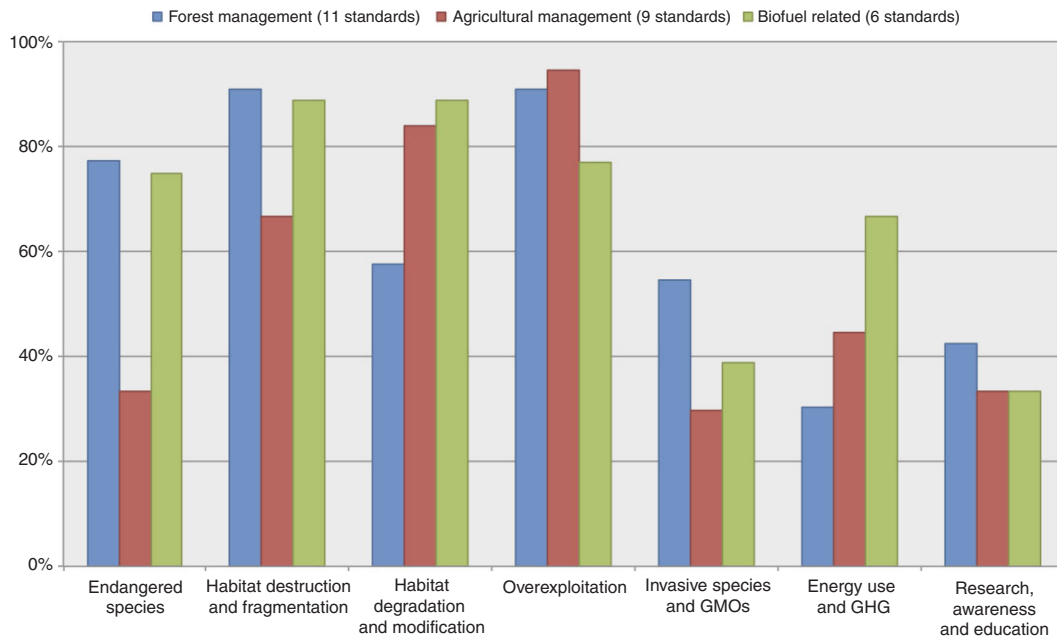

FIGURE 2 | Percentage of benchmark criteria complied with on a principle level for the three standard types, respectively. Well considered principles are those with >80% criteria complied with in total; Poorly considered principles are those with <50% criteria complied with in total.

conversion pressure is low. Nevertheless, the findings demonstrate that standards that are seemingly similar can be rather heterogeneous, and also that standards perceived as mainly associated with certain aspects can be highly stringent in regard to other aspects.

Regarding ecosystem conversion, forestry standards typically only protect areas that are considered HCV. They also tend to limit the HCV assessment requirements to include forested land only, i.e., they do not prevent conversion of highly biodiverse grasslands or wetlands into certified plantation forests.^e Agricultural standards cover more ecosystem types and typically do not provide for much flexibility: specific ecosystem types are either no-go areas or there are no conversion restrictions at all. The inflexibility that several of the agricultural standards apply may result in areas that could be beneficially converted into sustainable cultivation, such as some degraded grasslands, not being available. The biofuel-related standards, as already noted, are influenced by EU-RED and cover ecosystem conversion comprehensively, using a combination of HCV requirements and strict protection measures. Finally, some standards (EU Organic, NOP, and GGLS2) do not restrict land conversion at all. This may not be a large problem in countries with stringent legislation and sufficient enforcement capacity, but in countries where this is lacking, natural vegetation may be converted into certified agriculture, impacting biodiversity.

The fairness of the comparison between forestry and agricultural standards may be questioned, since certain benchmark criteria may be more connected to one type of land use than the other. This was however considered when interpreting the results.

It should be noted that the assessment outcome cannot be used as a basis for understanding the *effectiveness* of the standards. *First*, the assessment outcome clarifies whether a particular standard complies with a benchmark criterion, but it does not provide information about how this benchmark criterion is addressed. For instance, one standard may only require that a particular issue be *considered*, while another standard addresses the same issue by requiring *measurements, assessments, monitoring*, etc.—still, both these standards would be assessed as complying with the corresponding benchmark criteria. However, we observed that standards having a high level of compliance with the benchmark criteria are typically also more concrete in their way of addressing them. *Second*, in order to fully understand the effectiveness of sustainability standards to conserve biodiversity, field studies are necessary to measure actual results. *Third*, stringent sustainability standards may appear advantageous from a biodiversity perspective, but the effectiveness in conserving biodiversity depends on the relative importance of production under such standards compared to other production. Naturally, stringent certification schemes have to be widely applied in order to have a real effect on biodiversity conservation.

Besides for 'degraded land', all ecosystem types refer to unmanaged areas. 'P' indicates 'protected'; 'R' indicates 'restricted'; 'E' indicates 'encouraged'; 'HCV' indicates that conversion can be allowed, provided that the area is not regarded as HCV; 'N/R' indicates 'not relevant', i.e., the ecosystem type is not affected by the assessed standard.

¹For establishments of plantations only.

²Preservation of 'unproductive' nonforested land is recommended.

³To comply with the 'RTRS EU-RED Compliance Requirements for Producers'.

⁴To comply with the 'Bonsucro EU Production Standard'.

Given that certification involves additional costs (e.g., increased production cost, additional administration and fees to the certification scheme, certification body and auditors), biomass production

meeting sustainability standards may require support (e.g., establishment of markets for biofuels or other products that are based on such biomass) in order to become established and grow to significant scale.

However, where such ‘premium markets’ become established, production complying with more stringent standards may still not become significant in scale if production complying with less stringent standards also meets the requirements associated with the premium market and can support a market price that is too low from the perspective of the more stringent standards. Biofuels and other biomass products may also be produced based on many different feedstocks and some alternatives that comply with stringent standards may outcompete other more costly alternatives complying with the same standard. For example, sugarcane ethanol meeting the EU-RED requirements may outcompete more expensive European cereal ethanol meeting the same requirements. If this happens, EU-RED helps little in protecting biodiversity affected by European cereal production, which would then primarily be associated with food markets.

The biodiversity impact of sustainability standards may be impacted by unintended effects. For example, biomass production complying with sustainability standards may reach lower yields than conventional production (or production under less stringent standards). *Ceteris paribus*, lower yields mean that more land has to be brought into production to meet the demand and associated land use change may result in biodiversity impacts.⁴³

The extent to which sustainability standards protect biodiversity also depends on whether they stimulate innovation in land use aiming at protecting or enhancing biodiversity in the production landscape. Studies indicate that structuring and managing agricultural landscapes to host wild biodiversity can have neutral and even positive effects on agricultural output and livelihoods.³⁷ There are many examples of how perennial herbaceous and woody crops can be integrated into existing agricultural landscapes so as to enhance biodiversity and reduce impacts on water and soils.¹⁴

CONCLUSIONS AND RECOMMENDATIONS

Standards are not permanent, but they are continuously developed to reflect the state of understanding including availability of data and tools. Some standards are subject to frequent incremental updates while others undergo less frequent but more substantial changes. All the assessed standards can, to a varying degree, be improved to better consider biodiversity. The benchmark standard presented in this paper could be used as one basis in the development of more concrete criteria/indicators that fit into the scope of individual standards. The further

development of sustainability standards should aim for increased harmonization and reduction of heterogeneity of systems, while staying relevant for their intended production system. A balance needs to be found between stringency and comprehensiveness on the one hand and feasibility from a biomass-producer perspective on the other hand. It is important to avoid unnecessary requirements that increase administrative burden and cost without improving conservation outcome. Requirements that are too restricting/demanding may slow implementation and even prevent biomass production under the sustainability standard from reaching meaningful scale.

The use of generic standards, which have to be comprehensive in order to cover relevant aspects for a broad set of production systems, could be facilitated by (1) specifying for which production systems a criterion is valid, (2) defining different quantitative requirements for different production systems, or (3) developing substandards for different production systems. Heterogeneity of systems can also be reduced by considering multiple end uses of biomass in individual standards, when appropriate. SAN/RA, e.g., was initially applicable for food products only, but is now endorsed by RSB for production of biofuel feedstock. Consequently, producers can now sell their certified products at a premium on both the food market and the biofuel market, and traders can buy SAN/RA certified products and sell them on the EU-RED market.

Effectively realizing the objective to promote sustainable bioenergy requires flexibility in implementation to reflect local circumstances. In some countries, national legislation may already cover some of the requirements in a standard. If it is recognized that existing national legislation is sufficiently comprehensive and strict—and widely complied with—producers in such a country may be exempted from their reporting obligations concerning these requirements. Transitional rules might be used in situations where immediate full compliance with sustainability requirements is judged unattainable; less stringent initial requirements combined with a plan for development towards full compliance may be preferred where the alternative is more disruptive production for noncertified markets. A concrete example can be seen in the Fairtrade standard, which requires compliance with a basic set of criteria in the first year and then gradually extends compliance requirements to include an increasing number of criteria over time. This approach makes the first step into certification surmountable but, as the entire standard is highly comprehensive, constant improvement inevitable.

Similarly, allowing for some degree of flexibility may also help in addressing certain unwanted

effects, such as yield losses and nitrogen leaching associated with a transition to certified production and exclusion of suitable lands irrespective of conservation outcome. The possibility to produce for certified markets might be an incentive for developing land development plans balancing protection and production objectives in areas where much of the land is covered by ecosystems that are not allowed to be used under a sustainability standard. Such land development plans—where a certain share of these ecosystems are used for biomass production—might be preferred where the land conversion pressure is high.

The further development of certification standards could also consider approaches to stimulate innovation in land use that contributes positively to biodiversity conservation. Achieving this likely requires involvement of innovative practitioners, scientists, and indigenous land managers that are adapting, designing, and managing diverse types of landscapes to generate positive co-benefits for production, biodiversity, and local people. This work may increasingly need to consider adaptation needs arising as a consequence of climate change. A new role for actors involved with sustainability certification could be to facilitate processes where specific tools are used to engage stakeholders in defining and prioritizing sustainability objectives—including biodiversity conservation—in a specific local/regional context. Initiatives that show how this could take place include, e.g., ToSIA,¹¹² and attempts to identify and certify so-called ‘low-iLUC’ production.

As previously discussed, land management is characterized by trade-offs, and standards therefore need to consider the goals and objectives of different stakeholders in order to be effective. Therefore, it is necessary for standard developers to involve a wide range of stakeholders in the development process. By doing so, a standard can be developed to

reach acceptance among all stakeholders, be it NGOs, landowners, biofuel producers, or traders. This process can also contribute to the development of shared views among diverse stakeholders involved in the public debate about bioenergy sustainability in general.
