Chalmers Publication Library (CPL) offers the possibility of retrieving research publications produced at Chalmers University of Technology. It covers all types of publications: articles, dissertations, licentiate theses, masters theses, conference papers, reports etc. Since 2006 it is the official tool for Chalmers official publication statistics. To ensure that Chalmers research results are disseminated as widely as possible, an Open Access Policy has been adopted. The CPL service is administrated and maintained by Chalmers Library.

## N<sub>2</sub>O EMISSIONS FROM FLUIDIZED BED COMBUSTION

### INTRODUCTION

Nitrous oxide, N<sub>2</sub>O, was until recently regarded harmless. It is now known as a gas which contributes to the greenhouse effect as well as to the ozone layer depletion. In order to increase the knowledge about N<sub>2</sub>O and its role in the atmosphere, and about the chemistry of its formation and destruction in combustion processes, three workshops have been held (1, 2, 3).

The results presented in the two first workshops indicated that low-NO<sub>x</sub> techniques would also give low N<sub>2</sub>O emissions. However, this conclusion was based on erroneous measurements and most values were too high. Figure 1 shows the "old" correlation as well as the "new" values (here called "European" since the sampling technique in Europe was probably correct, whereas most American values were wrong). This was revealed by two US delegates (Kramlich and Muzio) during the last workshop. Hence, one of the major conclusions of this workshop was that sampling and analysis of N<sub>2</sub>O must be thoroughly examined and improved.

In spite of this, it was possible to conclude that N<sub>2</sub>O emissions from flame combustion are very low, 1–20 ppm, and that they are considerably higher from fluidized bed combustion.

### EXPERIMENTS

A survey made by Götaverken Energy during the spring of 1988 on a number of CFBs shows that the combustion of coal gives high values, peat both high and low, and wood and municipal waste result in low values (Table 1). This is in accordance with other measurements made in both Sweden and Finland regarding stationary and circulating beds burning all kinds of fuels. The N<sub>2</sub>O emission from a fluidized bed boiler is usually between 50 and 200 ppm.

N<sub>2</sub>O was measured in an 8-MW Götaverken Energy CFB boiler, as a part of a NO<sub>x</sub>-emission study by the Department of Energy Conversion at Chalmers University of Technology (4). The results show that the N<sub>2</sub>O emission in a CFB

- decreases when the temperature increases, Figure 2,
- increases when the excess air ratio increases, Figure 3,
- increases when the nitrogen content of the fuel increases, Figure 2 and Table 2.

The explanation of the results is not straightforward, since the chemistry of formation and destruction of  $\text{N}_2\text{O}$  is not well known. Also, the results of Figures 2 and 3 reflect what leaves a system in which the conditions vary. For instance, it is possible that the dependence of oxygen concentration shown in Figure 3 is partially a temperature dependence. The bottom bed temperature is kept constant whereas the top temperature drops when the excess air ratio increases.

### PRELIMINARY MODEL

Three formation mechanisms for  $\text{N}_2\text{O}$  have been proposed. They are

- homogeneous oxidation of volatile compounds containing nitrogen,
- heterogeneous oxidation of char nitrogen,
- heterogeneous reduction of NO on particle surfaces,

and two destruction mechanisms

- homogeneous reduction to  $\text{N}_2$ ,
- heterogeneous reduction of  $\text{N}_2\text{O}$  on particle surfaces.

### Volatile nitrogen

During devolatilization some of the fuel nitrogen is released, but not all. For instance the experiments of Freihaut and Seery (5) show that coal heated up at an intermediate rate up to  $900^\circ\text{C}$  releases approximately half of its nitrogen and the rest remains in the char (Figure 4).

A major source of  $\text{N}_2\text{O}$  is HCN, see for instance Kramlich et al. (6). At temperatures of interest for fluidized bed combustion only a small fraction of the volatile nitrogen forms HCN. Figure 4 shows that around 20% of the fuel nitrogen will appear as HCN under these temperature conditions. This situation is different from that in a flame, where much more HCN is released.

It is not fully known if other devolatilization products like  $\text{NH}_3$  also form  $\text{N}_2\text{O}$ . However, numerical calculations for post-flame conditions by Kramlich et al. (6) and experiments in a CFB by Åmand and Andersson (4) indicate that no  $\text{N}_2\text{O}$  is produced from  $\text{NH}_3$ .

Hence, a first assumption is that only HCN produces  $\text{N}_2\text{O}$ .

Calculations with a homogeneous reaction model (7) show that the conversion of 3000 ppm HCN in 5%  $\text{O}_2$ , 7%  $\text{H}_2\text{O}$ , 11%  $\text{CO}_2$  and 77%  $\text{N}_2$  in a well mixed reactor at constant temperatures ranging from 1050 K to 1300 K gives an almost constant maximum yield of  $\text{N}_2\text{O}$  of around 50%.

### Char nitrogen

The result of the heterogeneous reactions is much harder to estimate. The approach of Kramlich et al. (6), where he assumes that all char nitrogen forms  $\text{N}_2\text{O}$  and that all NO reduction results in  $\text{N}_2\text{O}$ , did not give any  $\text{N}_2\text{O}$  out of his reactor, but that could well be because of the high temperature of the system.

Experiments by de Soete (8) show that  $\text{N}_2\text{O}$  is formed when NO is reduced and also during combustion of char particles. Both NO and  $\text{N}_2\text{O}$  are reduced on the surface of a particle, NO partly producing  $\text{N}_2\text{O}$  and  $\text{N}_2\text{O}$  producing  $\text{N}_2$ . If the reduction of NO is faster than that of  $\text{N}_2\text{O}$ , the  $\text{N}_2\text{O}$  concentration increases.

De Soete showed that the reduction of  $\text{N}_2\text{O}$  on the surface of a particle is faster than the reduction of NO when the CO concentration is low. However, the NO reduction rate is much more sensitive to the concentration of CO than the rate of  $\text{N}_2\text{O}$  reduction. When the CO concentration increases, the  $\text{N}_2\text{O}$  reduction rate does not change, whereas the NO reduction rate increases (Figure 5). The experiments by de Soete were carried out on Pt-catalyst surfaces, not on sand or char surfaces. Still, a shift like the one shown in

Figure 5 can be expected also for such surfaces. In the bottom of the combustors the CO concentration is very high, sometimes several percent. This is a consequence of the staged combustion, the devolatilization and the low temperature of a fluidized bed combustor. The NO reduction can therefore be expected to be much faster than the N<sub>2</sub>O reduction, and the N<sub>2</sub>O concentration will increase.

Another finding of de Soete's is that a small part of the char nitrogen produces N<sub>2</sub>O during combustion ( $\approx 5\%$ ), whereas  $\approx 50\%$  of the char nitrogen produces NO (Figure 6). However, this is not only the result of direct oxidation of nitrogen to NO and N<sub>2</sub>O, but of the output from the porous reactor that a char particle is. Nitrogen oxidized to NO is reduced to N<sub>2</sub>O (and N<sub>2</sub>) during the transport out through the pores of the char particle.

### N<sub>2</sub>O reduction

Heterogeneous reduction is slow compared to the NO reduction but it will decrease the output of N<sub>2</sub>O.

A calculation with a homogeneous reaction scheme, Grimsberg (7), gives the destruction rate of N<sub>2</sub>O according to gas-phase chemistry. In Figure 7 it can be seen how much of the maximum yield of N<sub>2</sub>O that is reduced to N<sub>2</sub> in two seconds. Although the results of this calculation are only qualitative, the conclusion is evident: the influence of temperature is dramatic. At fluidized bed combustion temperatures the reduction of N<sub>2</sub>O is small compared to the case of flame combustion temperatures. This could explain the temperature effect seen in Figures 2 and 3, and also the difference between fluidized bed combustion and flame combustion.

### ESTIMATION

Using these data it is possible to form a rough estimation of the N<sub>2</sub>O concentration in the CFB furnace. Assume that a coal with 2% fuel nitrogen is used, comparable to the bituminous coal of the experiments of Figures 2 and 3. This can give 3200 ppm NO or 1600 ppm N<sub>2</sub>O if all is converted to either NO or N<sub>2</sub>O.

See Figure 8!

The source of  $\text{N}_2\text{O}$  formed from volatile nitrogen is assumed to be HCN. The fraction of nitrogen found in HCN compared to the total amount of fuel nitrogen is  $\approx 20\%$ . According to the kinetic model of Grimsberg, half of this amount produces  $\text{N}_2\text{O}$ . This gives a maximum concentration of volatile-nitrogen of 160 ppm  $\text{N}_2\text{O}$  (10% of 1600).

In a similar way the contribution from char nitrogen can be calculated. Half of the fuel nitrogen remains in the char and 5% of the char nitrogen produces  $\text{N}_2\text{O}$  giving 40 ppm (2.5% of 1600). At the same time 50% of the char nitrogen is converted into NO, which gives 800 ppm (25% of 3200).

These two formation mechanisms, from HCN and from char nitrogen, most probably take place at different locations in the combustion chamber. The  $\text{N}_2\text{O}$  formed from char nitrogen may appear where a major part of the combustion takes place, i.e. in the bottom bed.  $\text{N}_2\text{O}$  formed from HCN, on the other hand, should be formed up along the combustion chamber since HCN released during devolatilization is transported upwards at a high velocity. Also, the reactions are quite slow at the temperature conditions of a CFB.

The third formation mechanism of  $\text{N}_2\text{O}$ , NO reduced to  $\text{N}_2\text{O}$ , takes place throughout the combustion chamber, mainly above the bottom bed. Starting at 800 ppm NO this mechanism could, if efficient, produce large amounts of  $\text{N}_2\text{O}$ . In order to investigate this, NO was added to the combustion air of the 8-MW Götaverken Energy CFB boiler. The NO injected behaves like the NO released during combustion. As is seen in Figure 9, approximately 90% of the NO injected disappeared, but 10% was emitted as  $\text{N}_2\text{O}$ . This would result in 40 ppm  $\text{N}_2\text{O}$  from 800 ppm NO.

Hence it can be expected that the  $\text{N}_2\text{O}$  concentration in the bottom bed is around 40 ppm. The  $\text{N}_2\text{O}$  concentration should then increase up through the furnace, depending on the relative importance of the formation from HCN, the formation during the reduction of NO, and the destruction reactions. The maximum value that could be achieved in this case is  $40 + 160 + 40 = 240$  ppm  $\text{N}_2\text{O}$ .

One test run was carried out to investigate the gas composition with gas analysis at different locations in the combustion chamber. The result is shown in Figure 10. It is seen that the NO concentration decreases greatly up through the combustion chamber, whereas the  $\text{N}_2\text{O}$  concentration seems to be almost constant. However, the values presented in Figure 10 are the measured values not corrected for the different air flows at different heights. To make these values comparable, the lower ones (below 2 m) should

be multiplied by 0.6, the relative amount of primary air. This changes the gradient along the furnace, and  $\text{N}_2\text{O}$  actually increases up through the bed. The values in the bottom are different from those predicted. The NO concentration is much lower, 240 ppm instead of 800 ppm, and the  $\text{N}_2\text{O}$  concentration is higher, 60 ppm instead of 40 ppm. This can be explained by assuming a better NO reduction in the pores of the char particles than estimated above, which would reduce the NO concentration while increasing the  $\text{N}_2\text{O}$  concentration.

With the results from Figure 9, it is possible to estimate the  $\text{N}_2\text{O}$  produced through NO reduction. Starting with 240 ppm in the bottom bed, a calculation<sup>1</sup> gives that only 12 ppm  $\text{N}_2\text{O}$  is formed this way.

The sum of these two contributions, 60 ppm from the char nitrogen during combustion and 12 ppm from the NO reduction, is 72 ppm  $\text{N}_2\text{O}$ . This is only half the measured value in the outlet. The other half should come from volatile nitrogen. Hence, this rough calculation shows that the same amount of  $\text{N}_2\text{O}$  is produced from volatile nitrogen as from char nitrogen.

## CONCLUSIONS

Nitrous oxide,  $\text{N}_2\text{O}$ , is formed during combustion. In flames the  $\text{N}_2\text{O}$  is removed because of the fast destruction at high temperatures. At the temperatures of fluidized bed combustion the destruction is much slower and  $\text{N}_2\text{O}$  will leave the system, normally at a concentration of 50–200 ppm when burning coal. Using the results of the preliminary model in a CFB, it can be assumed that

- $\text{N}_2\text{O}$  is formed from char nitrogen in the bottom bed because of reactions in the pores of the particle.
- Only some  $\text{N}_2\text{O}$  is formed when NO is reduced during its journey up through the combustion chamber.
- $\text{N}_2\text{O}$  is formed from HCN. This is a slow process (taking seconds) and it therefore takes place principally above the bottom bed.

---

<sup>1</sup> 240 ppm NO can give 120 ppm  $\text{N}_2\text{O}$ . 10% of that is 12 ppm  $\text{N}_2\text{O}$ .
