ABSTRACT

We present a novel yet simple foreign function interface, designed for web-targeting Haskell dialects but also applicable to a wider range of high-level target languages. The interface automates marshalling, eliminates boilerplate code, allows increased sanity checking of external data, allows the import of functions as well as arbitrary expressions of JavaScript code, and is implementable as a plain Haskell '98 library without any modification to the Haskell compiler or environment.

We give an implementation of this interface for the JavaScript-targeting Haste compiler, and show how the basic implementation can be further optimized with minimal effort to perform on par with Haskell’s vanilla foreign function interface, as well as extended to support automatic marshalling of higher-order functions and automatic marshalling of host language exceptions. We also discuss how the interface may be extended beyond the web domain and implemented across a larger range of host environments and target languages.

1. INTRODUCTION

Interfacing with other languages is one of the more painful aspects of modern day Haskell development. Consider figure 1, taken from the standard libraries of GHC; a piece of code to retrieve the current time [19]. A relatively simple task, yet its implementation is surprisingly complex.

This code snippet is more akin to thinly veiled C code than idiomatic, readable Haskell; an unfortunate reality of working with the standard foreign function interface. When using compilers such as the Haste [9] and GHCJS [13] – GHC-based Haskell compilers which target the web browser – the situation is even worse. The modern web browser environment is highly reliant on callback functions and complex data types, none of which are trivial to pass through the FFI; the user has a wealth of high-level JavaScript libraries within arm’s reach, but is forced to go through the low-level gateway of the Haskell FFI [3] to touch them. While the example given in figure 1 certainly works when compiled with either Haste or GHCJS, it is not something the user would like to write.

Traditionally, Haskell programs have used the Foreign Function Interface extension to communicate with other languages. This works passably well in the world of native binary programs running on bare metal, where C calling conventions have become the de facto standard of foreign data interchange. The C language has no notion of higher-level data structures or fancy data representation, making it the perfect lowest common denominator interlingua for language to language communication: there is no ambiguity or clash between different languages’ built-in representation of various higher-level data structures, as there simply are no higher-level data structures on the interface level.

The same properties that make Haskell’s traditional foreign function interface a good fit for language interoperability make it undesirable as a vehicle for interfacing with the web-targeting code produced by compilers such as Haste and GHCJS: said Haskell implementations commonly rely on the browser environment for a large part of their runtime and internally use many of its native
high-level data structures and representations, making the forced low-level representations of the vanilla foreign function interface an unnecessary obstacle rather than a welcome common ground for data interchange. With this background, we believe that low-level interfaces such as the vanilla FFI are not ideally suited to the domain of functional languages targeting the web browser or other high-level environments. More specifically, we would like a foreign function interface for this domain to have the following properties:

- The FFI should automatically take care of marshalling for any types where marshalling is defined, without extra manual conversions or other boilerplate code.
- Users should be able to easily define their own marshalling schemes for arbitrary types.
- The FFI should allow importing arbitrary snippets of foreign code, not just named, statically known functions. This allows users to efficiently compose code from different libraries in a single import, as well as transform data which may be inefficient or cumbersome to import into Haskell as-is. To be clear, this capability is not intended to subsume writing proper, external JavaScript, but to give a means of reducing the impedance mismatch between Haskell and JavaScript without forcing the user to create stub after stub after stub.
- Finally, the FFI should be easy to implement and understand, ideally being implementable without compiler modifications, portable across Haskell implementations targeting high-level environments.

Making this list a bit more concrete in the form of an example, we would like to write high level code like that in figure 1, without having to make intrusive changes to our Haskell compiler. Contrasting this with the standard FFI code from figure 1:

- The low-level machine types are gone, replaced by a more descriptive record type, and so is the peeking and poking of pointers.
- The imported function arrives “batteries included”, on equal footing with every other function in our program. No extra scaffolding or boilerplate code is necessary.
- Whereas the code in figure 1 had to import the `gettimeofday` system call by name, its actual implementation given elsewhere, we have actually implemented its JavaScript counterpart at the location of its import from the building blocks available to us, without having to resort to external stubs.

To be clear, the idea of a higher-level foreign function interface is by no means novel in itself; there already exists a large body of work in this problem domain, solving many of the problems of figure 1, which is used here as an example mainly to establish the baseline for foreign function interfaces.

We discuss these related approaches in section 6.5, contrasting them with our approach. To our knowledge, our solution is the first to address all of the aforementioned criteria however. In particular, we are not aware of any other FFI framework that can be implemented entirely without compiler modifications.

**Our contribution.**

In section 2, we present a novel interface for a web-targeting Haskell dialect to interface with its JavaScript host environment at a high level of abstraction, and describe its implementation for the Haste compiler. The interface lets users import arbitrary JavaScript expressions in addition to the named functions traditionally importable through Haskell’s FFI, exploiting JavaScript’s built-in lambda abstraction for parameter interpolation in lieu of heavier and less portable solutions like anti-quotes. This enables users to create efficient bindings to foreign code with a potentially high impedance mismatch without having to pay with excessive boilerplate code. It allows for context dependent sanity checking of incoming data, improving the safety of foreign functions.

The interface makes use of dynamic code evaluation and the fact that JavaScript – the “machine language” of the web – is intended for human consumption to achieve a surprisingly lightweight implementation, which does not rely on modifications to the Haskell compiler; a feat which, to our knowledge, we are the first to perform.

The basic interface is implementable using plain Haskell ‘98 with the Foreign Function Interface extension, and is extensible by the user in the types of data which can be marshalled as well as in how said marshalling is performed.

In section 3 we discuss various safety and performance concerns about our implementation, and show how these concerns can be alleviated by reaching outside the confines of Haskell ’98.

In section 4 we show the flexibility of our design by using it to implement marshalling of higher-order functions between Haskell and JavaScript, as well as a mechanism for automatically marshalling JavaScript exceptions into Haskell equivalents. We also discuss how to remove dynamic code evaluation from the equation with a slight modification to the Haskell compiler in use.

## 2. AN FFI FOR THE MODERN WEB

### 2.1 The interface

This section describes the programmer’s view of our interface and gives examples of its usage. The Haskell formulation of the interface is given in figure 3.

As the main purpose of a foreign interface is to shovel data back and forth through a rift spanning two separate programming worlds, it makes sense to begin the description of any such interface with one central question: what data can pass through the rift and come out on the other side still making sense?

The class of data fulfilling this criterion is embodied in an abstract `HostAny` data type, inhabited by host-native representations of arbitrary Haskell values. Its representation is not fixed, but rather a reference to a value of any type representable in the underlying host language. From the Haskell point of view, its representation can be seen as a completely opaque reference. Hence, the only parts of the library that can interact directly with a `HostAny` value are the ones explicitly imported through the vanilla FFI. A data type is considered to be marshallable if and only if it can be converted to `HostAny` and back again using some such imported function or combination thereof.

Having established the class of types that can be marshalled, we can now give a meaningful definition of `importable` functions: a
In the rest of section 2, we give an implementation of the basic
backs to their JavaScript equivalents.
order function, automatically converting user-provided Haskell call-
= host "hello, world"
function can be imported from the host language into our Haskell
program if and only if:
• all of its argument types are convertible into HostAny;
• its return type is convertible from the host-native HostAny;
• its return type resides in the IO monad, accounting for the
possibility of side effects in host language functions.
The JavaScript implementation of these two functions is simply the
identity function. As explained in section 2, HostAny is simple
an opaque reference to Haskell, but to JavaScript a reference is
just another dynamically typed value. These functions are essen-
tially a slightly roundabout way to coerce, rather than convert, base
type values into HostAny without having to know anything about
the compiler’s FFI implementation or internal representation of the
base types. The same approach is used for the other base types.

At first glance, it might seem strange to separate
= host "window.cancelAnimationFrame"
cancelFrame :: FrameHandle → IO ()
cancelFrame = host "window.cancelAnimationFrame"

The resulting code is straightforward and simple, even though it
performs the rather non-trivial task of importing a foreign higher-
order function, automatically converting user-provided Haskell call-
backs to their JavaScript equivalents.

In the rest of section 2, we give an implementation of the basic
Haskell ‘98 interface for the Haste compiler. We then extend it
with features requiring some extensions to Haskell ‘98 in section 4,
to arrive at the complete interface presented here.

### 2.2 Implementing marshalling

As usual in the functional world, we ought to start with the base

case: implementing marshalling for the base types that lie at the
bottom of every data structure.

This is a simple proposition, as this is the forte of the vanilla foreign
function interface.

```haskell
foreign import stdcall intToAny :: Int → HostAny
foreign import stdcall anyToInt :: HostAny → IO Int

instance ToAny Int
instance FromAny Int

instance ToAny a ⇒ Import (IO a)
instance FromAny a ⇒ FromAny (IO a)
```

The data we want to convert, the structure of our desired host lan-
gerage representation of two values may well be different even when
their Haskell representations are quite similar, or even identical.

Hence, we need to put the power over this decision into the hands
of the user, providing functionality to build as well as inspect dic-
tories:

```haskell
mkDict :: (ToAny a, Exportable b) ⇒ ToAny (a → b)
getMember :: FromAny a ⇒ FromAny (b → a)
```

For dictionaries, the conversion is not as clear-cut. Depending on
the data we want to convert, the structure of our desired host lan-
gerage representation of two values may well be different even when
their Haskell representations are quite similar, or even identical.

Hence, we need to put the power over this decision into the hands
of the user, providing functionality to build as well as inspect dic-
tories.

We will need three basic host language operations: creating a new
dictionary, associating a dictionary key with a particular value, and
looking up values from dictionary keys. From these we construct
two functions to marshal sum and product types to and from dic-
tories: mkDict which creates dictionaries from association lists,
and getMember, which looks up dictionary values by key. While a
Map would normally be the go-to data structure for describing dic-
tories, mkDict only iterates over its argument in order to add the

A JavaScript array is quite a different beast from an “actual” array
as seen in C, making the push operation more efficient than one
would normally expect.
Implementing the host function – the function by which JavaScript functions are imported into Haskell – turns out to be slightly trickier than marshalling data between environments. We want to be able to use a single function to import any JavaScript function, using the declared Haskell type of the imported function to determine its arity, argument types and return type. There is a well known way to accomplish this, colloquially known as “the printf trick” [1], which uses an inductive class instance to successively build up a list of arguments over repeated function applications, and a base case instance to perform some computation over said arguments after the function in question has been fully applied. In the case of the host function, that computation would be applying a foreign function to said list of arguments. This suggests the following class definition.

2.3 Importing functions

Implementing the host function – the function by which JavaScript functions are imported into Haskell – turns out to be slightly trickier than marshalling data between environments. We want to be able to use a single function to import any JavaScript function, using the declared Haskell type of the imported function to determine its arity, argument types and return type. There is a well known way to accomplish this, colloquially known as “the printf trick” [1], which uses an inductive class instance to successively build up a list of arguments over repeated function applications, and a base case instance to perform some computation over said arguments after the function in question has been fully applied. In the case of the host function, that computation would be applying a foreign function to said list of arguments. This suggests the following class definition.
return value is marshalled back into Haskell through fromAny and returned to the caller of \( f \). The apply function which performs the actual application is very simple:

```haskell
function(f, args) { return f.apply(null, args); }
```

With this, we have all the building blocks required to implement the host function. With all the hard work already done, the implementation is simple. For the sake of brevity, we assume the existence of a host language specific HostString type, which may be passed as an argument over the vanilla foreign function interface, and a function toHostString :: String \( \rightarrow \) HostString.

```haskell
foreign import stdcall
eval :: HostString \rightarrow\text{HostFun}

host s = import_ f []
where
  f = eval (toHostString s)
```

The foreign eval import brings in the host language’s evaluation construct. Recall that one requirement of our method is the existence of such a construct, to convert arbitrary strings of host language code into functions or other objects. eval is then used to create a function object – represented as a HostFun – which is used to create the aforementioned Haskell function \( f \). This is all we need to be able to import first order JavaScript functions such as the motivating example in figure 2.

3. Optimizing for Safety and Performance

While the implementation described up until this point is more or less feature complete, its non-functional properties can be improved quite a bit if we allow ourselves to stray from the tried and true, but slightly conservative, path of pure Haskell ‘98. Aside from implementation specific tricks – exploiting knowledge about a particular compiler’s data representation to optimize marshalling, or even completely unroll and eliminate some of the basic interface’s primitive operations, for instance – there are several general optimizations we can apply to significantly enhance the performance and safety of our interface.

3.1 Eliminating argument passing overheads

The performance-minded reader may notice something troubling about the implementation of \texttt{import}:: the construction of an intermediate list of arguments. Constructing this intermediate list only to convert it into a host language suitable representation which is promptly deconstructed as soon as it reaches the imported function takes a lot of work. Even worse, this work does not provide any benefit for the task to be performed: applying a foreign function. By the power of rewrite rules [15], we can eliminate this pointless work in most cases by specializing the host function’s base case instance for different numbers of arguments. In addition to the general apply function we define a series of apply0, apply1, etc. functions, one for each arity we want to optimize function application for. The actual specialization is then a matter of rewriting host calls to use the appropriate application function.

Figure 6 gives a new implementation of the base case of the \texttt{Import} class which includes this optimization, replacing the one given in section 2.

3.2 Preventing code injection

Meanwhile, the safety-conscious reader may instead be bristling at the thought of executing code contained in something as egregiously untyped and untrustworthy as a common string. Indeed, by allowing the conversion of arbitrary strings into functions, we’re setting ourselves up for cross-site scripting and other similar code injection attacks!

While this is indeed true in theory, in practice, accidentally passing a user-supplied string to the host function, which in normal use ought to occur almost exclusively on the top level of a module, is a quite unlikely proposition. Even so, it could be argued that if it is possible to use an interface for evil, its users almost certainly will at some point.

Fortunately, the recent 7.10 release of the GHC compiler, on which both Haste and GHCJS are based, gives us the means to eliminate this potential pitfall. The \texttt{StaticPointers} extension, its first incarnation described in [10], introduces the \texttt{static} keyword, which is used to create values of type \texttt{StaticPtr} from closed expressions. Attempting to turn any expression which is not known at compile time into a \texttt{StaticPtr} yields a compiler error.

Implementing a \texttt{safe} host function which can not be used to execute user-provided code becomes quite easy using this extension and the basic host function described in section 2, at the cost of slightly more inconvenient import syntax:

```haskell
safe_host :: Import f \Rightarrow\text{StaticPtr String} \rightarrow f
safe_host = host . deRefStaticPtr
```

```
safe_hello :: IO ()
safe_hello = safe_host $
  static "() \Rightarrow alert('Hello, world!')"
```

3.3 Relying on eval

Relying on eval to produce our functions allows us to implement our interface in pure Haskell ‘98 without modifying the Haskell compiler in question, making the interface easy to understand, implement and maintain. However, there are reasons why it may be
in the implementor’s best interest to forgo a small bit of that simplicity.
The actual call to eval does not meaningfully impact performance: it is generally only called once per import, the resulting function object cached thanks to lazy evaluation. However, its dynamic nature does carry a significant risk of interfering with the ability of the host language’s compiler and runtime to analyze and optimize the resulting code. As discussed in section 5, this effect is very much in evidence when targetting the widely used V8 JavaScript engine.

In the JavaScript community, it is quite common to run programs through a minifier — a static optimizer with focus on code size — before deployment. Not only do such optimizers suffer the same analytical difficulties as the language runtime itself from the presence of dynamically evaluated code, but due to the heavy use of renaming often employed by minifiers to reduce code size, special care needs to be taken when writing code that is not visible as such to the minifier: code which is externally imported or, in our case, locked away inside a string for later evaluation.

Noting that virtually every sane use of our interface evaluates a static string, a solution presents itself: whenever the eval function is applied to a statically known string, instead of generating a function call, the compiler splices the contents of the string verbatim into the output code instead.

This solution has the advantage of eliminating the code analysis obstacle provided by eval: for the case when our imported code is statically known (which, as we noted before, is a basic sanity property of foreign imports), while preserving our library’s simplicity of implementation. However, it also has the disadvantage of requiring modifications to the compiler in use, however slight, which increases the interface’s overall complexity of implementation.

4. EXTENDING OUR INTERFACE

While the interface described in sections 2 and 3 represents a clear raising of the abstraction layer over the vanilla foreign function interface, it is still lacking some desirable high level functionality: marshalling of higher order functions, exception handling and generic marshalling. In this section we demonstrate the flexibility of our interface by showing how this functionality can be implemented on top of it.

4.1 Dynamic function marshalling

Dynamic imports.

One appealing characteristic of our interface is that it makes the marshalling of functions between Haskell and the host language easy. In the case of passing host functions into Haskell, the import function used to implement host has already done the heavy lifting for us. Only adding an appropriate FromAny instance remains.

Due to the polymorphic nature of functions, however, we must resort to using some language extensions to get the type checker to accept our instance: overlapping instances, flexible instances, and undecidable instances. Essentially, the loosened restrictions on type class instances allow an Import instance to act as a synonym for FromAny, allowing host language functions to return functions of any type admissible as an import type by way of the host function.

```
instance Import a ⇒ FromAny a where
  fromAny f = return (import_ f [])
```

4 The main reason for eval getting called more than once being unwise inlining directives from the user.

Passing functions to foreign code.

Passing functions the other way, out of Haskell and into our host language, requires slightly more work. While we already had all the pieces of the dynamic import puzzle at our disposal through our earlier implementation of host, exports require one more tool in our toolbox: a way to turn a Haskell function into a native host language function.

Much like the apply primitive used in the implementation of host, the implementation of such an operation is specific to the host language in question. Moreover, as we are dealing with whatever format our chosen compiler has opted to represent functions by, this operation is also dependent on the compiler.

In order to implement this operation, we assume the existence of another function hsfun.to.host, to convert a Haskell function \( f \) from \( n \) HostAny arguments to a HostAny return value \( r \) in the IO monad into a host language function which, when applied to \( n \) host language arguments, calls \( f \) with those same arguments and returns the \( r \) returned by \( f \).

```
foreign import stdcall hsfun.to.host
  :: (HostAny → ... → HostAny) → HostFun

hsfun.to.host :: Exportable f ⇒ f → IO HostFun
hsfun.to.host f =
  hsfun.to.host 'fmap' newStablePtr (mkHostFun f)
```

Just being able to pass Haskell functions verbatim to the host language is not enough. The functions will expect Haskell values as their arguments and return other Haskell values; we need to somehow modify these functions to automatically marshal those arguments and return values. Essentially, we want to map fromAny over all input arguments to a function, and toAny over its return values. While superficially similar to the implementation of the Import class in section 2.3, this task is slightly trickier: where import_ modifies an arbitrary number of arguments and performs some action with respect to a monomorphic value — the HostFun representation of a host language function — we now need to do the same to a variadic function.

Modifying variadic functions using type families.

A straightforward application of the printf trick used to implement Import is not flexible enough to tackle this problem. Instead, we bring in yet another language extension, closed type families [8], to lend us the type level flexibility we need. We begin by defining the Exportable type class which denotes all functions that can be exported into JavaScript, and a closed type family describing the
type level behavior of our function marshalling.

```haskell
type family Host a where
  Host (a → b) = HostAny → Host b
  Host (IO a) = IO HostAny

class Exportable f where
  mkHostFun :: f → Host f

This is relatively straightforward. Inspecting the Host type family, we see that applying mkHostFun to any eligible function must result in a corresponding function of the same arity – hence the recursive type family instance for \(a \rightarrow b\) – but with its arguments and return value replaced by HostAny.

Giving the relevant Exportable instances is now mostly a matter of making the types match up, and concocting a ToAny instance is only a matter of composing our building blocks together.

```haskell
instance ToAny a ⇒ Exportable (IO a) where
  mkHostFun = fmap toAny
```

```haskell
instance (FromAny a, Exportable b) ⇒ Exportable (a → b) where
  mkHostFun f =
    mkHostFun . f . unsafePerformIO . fromAny

instance Exportable f ⇒ ToAny f where
  {-# NOINLINE toAny #-}
  toAny = unsafePerformIO . hsfun_to_host
```

The one interesting instance here is that of the inductive case, where we use FromAny in conjunction with unsafePerformIO to marshal a single function argument. While using fromAny outside the IO monad is unsafe in the general case as explained in section 2, this particular instance is completely safe, provided that mkHostFun is not exported to the user, but only used to implement the ToAny instance for functions.

When a function is marshalled into a HostAny value and subsequently applied, fromAny will be applied unsafely to each of the marshalled function's arguments. There are two cases when this can happen: either the marshalled function is called from the host language, or it is marshalled back into Haskell and then applied. In the former case, the time of the call is trivially well-defined assuming that our target language is not lazy by default. In the latter case, the time of the call is still well-defined, as our interface only admits importing functions in the IO monad.

Slightly more troubling is the use of unsafePerformIO in conjunction with hsfun_to_host. According to [17], the creation of stable pointers residing in the IO monad – the reason for hsfun_to_host residing there as well – is to avoid accidentally duplicating the allocation of the stable pointer, something we can avoid by telling the compiler never to inline the function, ever. It is also worth pointing out that the concern over duplicating this allocation is only valid where the implementation also has the aforementioned space leak problem, in which case the alternative implementation given in section 6.3 should be preferred anyway.

**Marshalling pure functions.**

The above implementation only allows us to pass functions in the IO monad to foreign code, but we would also like to support passing pure functions. There are two main obstacles to this:

- The `hsfun_to_host` function expects a function in the IO monad.
- Instantiating Exportable for any type `ToAny t ⇒ t` would accidentally add a ToAny instance for *any type at all*. Even worse, this instance would be completely bogus for most types, always treating the argument to its `toAny` implementation as a function to be converted into a host language function!

We sidestep the first problem by assuming that `hsfun_to_host` can determine dynamically whether a function is pure or wrapped in the IO monad, and take action accordingly. Another, slightly more verbose, possibility would be to alter the implementation of our marshalling code to use either `hsfun_to_host` or a function performing the same conversion on pure functions, depending on the type of function being marshalled.

Looking closer at the problematic `ToAny` instance, we find that the `Exportable t ⇒ ToAny t` instance provides `ToAny` for any `Exportable type`, and the `ToAny t ⇒ Exportable t` instance provides `Exportable` in return, creating a loop which creates instances for both type classes matching any type.

The `ToAny t ⇒ Exportable t` instance is necessary for our type level recursion to work out when marshalling pure functions, but we can prevent this instance from leaking to `ToAny` where it would be unreasonably broad by replacing our `ToAny` function instance with two slightly more specific ones. This is the reason for having two separate type classes for marshalling data into and out of Haskell. We need to be able to export pure functions from Haskell while for safety reasons not allowing them to be imported, and we want to avoid creating the problematic unlimited export instance described above; forcing importable types to be exportable and vice versa disallows both.

Figure 7 gives our final implementation of dynamic function exports. Looking at this code we also see why the use of closed type families are necessary: the open type families originally introduced by Chakravarty et al [5] do not admit the overlapping type equations required to make pure functions an instance of `Exportable`.

```haskell
mkHostFun f =
  unsafePerformIO . hsfun_to_host
```

{-# NOINLINE toAny #-}

\[
toAny = unsafePerformIO \cdot hsfun_to_host
\]
import Foreign.StablePtr
import System.IO.Unsafe

foreign import stdcall
  
hsfun.to.host :: StablePtr a -> HostFun

hsfun.to.host :: Exportable f ⇒ f → IO HostFun
hsfun.to.host f =
  .hsfun.to-host 'fmap' newStablePtr (mHostFun f)

type family Host a where
  Host (a → b) = HostAny ⇒ Host b
  Host (IO a) = IO HostAny
  Host a = HostAny

class Exportable f where
  mHostFun :: f → Host f

instance (ToAny a, Host a ~ HostAny) ⇒ Exportable a where
  mHostFun = toAny

instance (FromAny a, Exportable b) ⇒
  ToAny (a → b) where
  {-# INLINE toAny #-}
  toAny = unsafePerformIO . hsfun.to_host

instance ToAny a ⇒ ToAny (IO a) where
  {-# INLINE toAny #-}
  toAny = unsafePerformIO . hsfun.to_host

Figure 7: Dynamic function exports implemented on top of our interface

4.2 Static function exports
Very rarely are users prepared to abandon person-decades of legacy code; to reach these users, the ability to expose Haskell functionality to the host language is important. Alas, being implemented as a library, our interface is not capable of foreign export declarations – the vanilla FFI’s mechanism for making Haskell functions available to foreign code. We can, however, implement a substitute on top of it.

Rather than writing a library which when compiled produces a shared library for consumption by a linker, we give the user access to a function export which when executed stores an exported function in a known location, where foreign language code can then access it. While this may seem like a silly workaround, this is how JavaScript programs commonly “link against” third party libraries. Using the function marshalling implemented in section 4.1, implementing export becomes a mere matter of passing a function to the host language, which then arranges for the function to be available in a known, appropriate location.

export :: ToAny f ⇒ String → f → IO ()
export =
  host "(name, f) ⇒ window['haskell'][name] = f;"

4.3 Generic marshalling
Returning to our motivating example with figure 2, we note a conspicuous absence: the UTCTime instance of FromAny is not defined, yet it is still used by the host function in the definition of getCurrentTime. Although the instance can be defined in a single line of code, it would still be nice if we could avoid the tedium of writing that one line altogether. As stated in section 2.2, any non-arrow Haskell type can be represented using a combination of arrays and dictionaries. Using one of the generic programming frameworks offered by Haskell, such as GHC generics [11] or Template Haskell [18], it is possible to create a default instance of the marshalling type classes, applicable to any Haskell type.

As the implementation of such an instance is neither novel nor particularly interesting in the context of this paper, we refer the reader to the one used by the aeson package for encoding and decoding of JSON values [14]. This default instance provides the final piece of the puzzle required to use the interface as presented in figure 2.

4.4 Marshalling JavaScript exceptions
Trapping errors in foreign C code is relatively straightforward, albeit cumbersome, owing to the relative absence of structured error handling in C. However, when interacting with a higher-level language, one must take into account the risk of exceptions being raised in any imported foreign code. In the basic Haste.Foreign interface, such exceptions must be manually handled lest they terminate the enclosing Haskell program much like a segmentation fault in imported C code would terminate a native Haskell program.

Thankfully, we can leverage the higher-order import capabilities described in section 4 to catch JavaScript exceptions and re-throw them within Haskell’s exception handling framework. We import a JavaScript function catchJS which accepts an exception handler function and an IO computation as its arguments. When called, catchJS executes IO computation inside a try-catch block. If an exception is raised, it is passed to the exception handler function which then takes appropriate action.

catchJS may be used similarly to Haskell’s catch function to catch exceptions in foreign functions where they are expected to occur. However, it is not necessarily the case that we always want to handle exceptions right at the call site of a foreign function – quite the opposite! Instead, we can create an exception-safe equivalent to host which uses catchJS to dispatch all calls to functions imported through it, with an exception handler function that simply re-throws the JavaScript exception wrapped in a Haskell exception. The wrapped exception can then be caught anywhere a “normal” Haskell exception could be caught. A complete implementation of this extension is given in figure 8.

An interesting side-effect of this approach to exception handling and the fact that JavaScript syntax errors are catchable exceptions is that the exception-safe host function is not only catch dynamic errors, but incorrectly written foreign imports as well.

It should be noted that this approach incurs a performance penalty due to the extra function call and marshalling required to dispatch a function, as further discussed in section 5.

5. PERFORMANCE
While increased performance is not a major motivation for this work, it is still important to ascertain that using our library does not entail a major performance hit. To determine the runtime performance of our interface vis a vis the vanilla FFI – a useful baseline for performance comparisons – we have benchmarked a reference implementation of our interface against the vanilla FFI, both implemented for the Haste compiler.

While benchmarking code outside the context of any particular application is often tricky and not necessarily indicative of whole system performance, we hope to give a general idea of how our library fares performance-wise in several different scenarios. To this end, several microbenchmarks were devised:

- Outbound, which applies a foreign function to several arguments of type Double. The function’s return value is discarded, in order to only measure outbound marshalling over-
catchJS :: (ToAny a, FromAny a) ⇒ (String → IO (I)) → IO a → IO a
catchJS = "(handle, act) ⇒ \{
  try {
    return act();
  }\catch (ex) { handle(ex.toString()); }
"

Figure 8: Marshalling JavaScript exceptions

- **In-out.** which applies a foreign function to several double arguments and marshals its return value, also of type double, back into Haskell land. This measures inbound as well as outbound marshalling of primitive types.
- **Product types.** which benchmarks the implementation of get currentTime given in figure 2 against the equivalent implementation given in figure 1, both modified to accept an UTCTime value as input in addition to returning the current time, in order to measure outbound marshalling of product types as well as inbound.
- **HOF import.** which calls a higher-order function f using both the vanilla FFI and our method, with a function over a single double value as its argument. The only purpose of f is to call its argument repeatedly, evaluating the speed with which a higher-order Haskell function may be called from external code in addition to the speed of marshalling itself.

These functions were then applied 500000 times in two different contexts: one tight, strict, tail recursive loop, intended to produce as efficient code as possible; and one which simply consists of running mapM over a list containing 500000 elements, to obtain higher-level code which is harder to optimise and analyse for strictness.

The resulting programs, compiled with version 0.5.4.2 of the Haste compiler which incorporates all the optimizations described in section 3, were then repeatedly executed using version 4.2.2 of the Node.js JavaScript interpreter, and the average run times of the programs using our interface compared against the average run times of their FFI counterparts. The benchmarks were executed on a Lenovo ThinkPad X230 laptop running Debian GNU/Linux, equipped with an Intel i5 3210M CPU and 8 GB of RAM.

The results for each benchmark are given in table 1 as the ratio of the run time for our library over the run time for the vanilla FFI.

### Table 1: Execution times as fractions of FFI execution times

Benefits of optimization.

In contrast, the performance hit when using the exception-safe version defined in section 4.4 is huge. This is by no means surprising: using the exception-safe version entails marshalling no less than two additional higher-order functions, which is quite a bit heavier than the otherwise very lightweight marshalling performed for plain numbers.

### In-out.

Moving on to the benchmarks where we actually marshal incoming data, the picture is much the same as for the outbound benchmark. The performance hit from the exception marshaller becomes even more problematic here, as the return value of the function needs to be marshalled first into Haskell, then back into JavaScript for the exception handler, and finally back into Haskell again.

### Product types.

Our interface shows a small performance advantage when it comes to marshalling more complex values, being 5 – 20 % faster depending on the loop. Our assumption about peeking and poking at pointers being suboptimal in an environment where such operations are considerably more expensive than on bare metal seems to have been correct.

Worth noting is that the performance overhead of the exception marshaller becomes significantly less prohibitive in this benchmark, as the complexity of marshalling grows. This indicates that while expensive compared to the minimal marshalling required for base types, exception safety may not be all that expensive after all, when calling a function which performs actual work.

### HOF import.

Our interface seems to compare favorably to the vanilla FFI for this case, although the performance gain difference is quite minimal. This is to be expected, as the heavy lifting required to export Haskell functions into JavaScript is relatively similar and quite heavy regardless of how the relatively lightweight marshalling of the function’s base type arguments is carried out. Again, it is worth pointing out how the significance of the exception marshaller’s performance penalty dwindles as the marshalling process as a whole grows heavier.

### Performance verdict: acceptable.

Judging by these numbers the performance of our library is quite acceptable, with the exception of the heavy toll taken by the exception marshaller on the less complex marshalling cases. Interestingly, the optimization described in section 3.3 does not impact performance measurably in these benchmarks. If any performance benefit is to be had from this optimization, is will likely come from increased opportunities for minifiers and JavaScript engines to perform inlining over more complex programs.

It is encouraging that our interface’s intended use case - marshalling
more complex types and higher-order functions - is showing tangible performance benefits in addition to the added convenience it affords the user. For code which has no choice but to make a large number of calls to low level host language functions over primitive types in performance critical loops, using the vanilla FFI instead, or at least handling JavaScript exceptions in foreign code instead of relying on our library’s exception marshaller, may be an attractive option to reduce the performance penalty incurred by our interface in unfavorable circumstances, allowing the user to have the FFI cookie and eat it at the same time.

The benchmarks used here are available online from our repository at https://github.com/valderman/ffi-paper.

6. DISCUSSION
While two of the three main limitations our interface places on its host language – the presence of a dynamic code evaluation construct and support for first class functions – have hopefully been adequately explained, and their severity slightly alleviated, in sections 2 and 3.3, there are still several design choices and lingering limitations that may need further justification.

6.1 fromAny and error handling
The fromAny function used to implement marshalling in section 2 is by definition not total. As its purpose is to convert dynamically typed JavaScript values into statically typed Haskell values, from the simplest atomic values to the most complex data structures, the possibility for failure is apparent. Why, then, does its type not admit the possibility of failure, for instance by wrapping the converted value in a Maybe or Either?

Recall that fromAny will almost always be called when automatically converting arguments to and return values from callbacks and imported foreign functions respectively. In this context, even if a conversion were to fail with a Left “Bad conversion” error, there is no way for this error value to ever reach the user. The only sensible action for the foreign call to take when encountering an error value would be to throw an exception, informing the user “out of band” rather than by somehow threading an error value to the entire call. It is then simpler, as well as reducing the amount of error checking overhead necessary, to trust that the foreign code in question is usually well behaved and throw the previously mentioned exception immediately on conversion failure rather than taking a detour via error values, should this trust prove to be misplaced.

It should also be noted that the basic interface does neither handle syntax errors nor exceptions thrown from foreign code: it is the responsibility of the user.

6.2 Generalising to other languages
The implementation so far has been quite clearly focused on the needs of web-targeting Haskell dialects. However, the interface and library described should be portable across other host languages with relative ease, provided that they have the following properties:

Dynamically typed. The reliance on the HostAny type to represent host language values makes support for statically typed host languages very cumbersome, at best.

Garbage collected. Our interface completely ignores something which very much concerns traditional foreign function interfaces: ownership and eventual deallocation of memory. This careless behavior is enabled by the fact that the host language is assumed to be garbage collected. Removing garbage collection from the equation would land us in a position much more similar to the vanilla FFI, albeit with less restrictions on marshallable types.

Dynamic code evaluation. The ability to import foreign code without compiler modification relies crucially on the ability of the host language to execute arbitrary strings of code. While this restriction can be lifted with a compiler modification as described in 3.3, this diminishes the utility of the interface, limiting the portability and ease of implementation that are some of its greatest strengths.

Higher order. Dynamic code evaluation is not much use if we can’t evaluate a piece of code and get a function object back – there is nothing for our Haskell program to call! While it is certainly conceivable to re-evaluate strings of host language code anew on each function application, with arguments spliced into the evaluated program, this strikes us as an approach which is both brittle and slow, leading us to conclude that our interface would fare quite badly in a first order language.

Linguages that fulfill these criteria and might make attractive targets for porting include Python, PHP and Ruby. While our interface should be portable to any such language, we have yet to implement our interface for any non-JavaScript environment.

6.3 Limitation to garbage collected host languages
The observant reader may notice that up until this point, we have completely ignored something which very much concerns traditional foreign function interfaces: ownership and eventual deallocation of memory.

Our high level interface depends quite heavily on its target language being garbage collected, as having to manually manage memory introduces significant boilerplate code and complexity: the very things this interface aims to avoid. As target platforms with garbage collection having to deal with low level details such as memory management is the core motivation for this work, rectifying this issue does not fall within the scope of this paper.

Even so, memory management does rear its ugly head in section 4.1, where stable pointers are used to pass data unchanged from Haskell into our host language, and is promptly ignored: note the complete absence of calls to freeStablePtr. Implementing our interface for the Haste compiler, this is not an issue: Haste makes full use of JavaScript’s garbage collection capabilities to turn stable pointers into fully garbage collected aliases of the objects pointed to. It is, however, quite conceivable for an implementation to perform some manual housekeeping of stable pointers even in a garbage collected language, in which case this use of our interface will cause a space leak as nobody is keeping track of all the stable pointers we create.

As the stable pointers in question are never dereferenced or otherwise used within Haskell, this hypothetical space leak can be eliminated by replacing stable pointers with a slight bit of unsafe, implementation-specific magic.

```haskell
import Unsafe.Coerce
import Foreign.StablePtr hiding (newStablePtr)

data FakeStablePtr a = fakeStablePtr :: a -> FakeStablePtr a
newStablePtr :: a -> StablePtr
newStablePtr = unsafeCoerce . fakeStablePtr
```

The FakeStablePtr type and the function by the same name are used to mimic the underlying structure of StablePtr. This makes its exact implementation specific to the Haskell compiler in question, unlike the “proper” solution based on actual stable pointers. The Haste compiler, being based on GHC, has a very straightforward representation for stable pointers, merely wrapping the “machine” level pointer in a single layer of indirection, giving us the following implementation of fake stable pointers:
data FakeStablePtr a = Fake !a
fakeStablePtr = Fake

Thus, we may choose our implementation strategy depending on the capabilities of our target compiler. For a single implementation targeting multiple platforms however, proper stable pointers are the safer solution.

6.4 Restricting imports to the IO monad

The interface presented in this paper does not support importing pure functions; any function originating in the host language must be safely locked up within the IO monad. This may be seen as quite a drawback, as a host language function operating solely over local state is definitely not beyond the realms of possibility. Looking at our implementation of function exports for pure functions, it seems that it would be possible to implement imports in a similar way, and indeed we could.

However, “could” is not necessarily isomorphic to “should”. Foreign functions do, after all, come from the unregulated, disorderly world outside the confines of the type checker. Haskell’s type system does not allow us to mix pure functions with possibly impure ones, and for good reason. It is not clear that we should lift this restriction just because a function is defined in another language. Moreover, as explained in section 2, marshaling inbound data is in many cases an inherently effectful operation, particularly when involving complex data structures. Permitting the import of pure functions, knowing fully well that a race condition exists in the time window between the import’s application and the resulting thunk’s evaluation, does not strike us as a shining example of safe API design.

Better, then, to let the user import their foreign code in the IO monad and explicitly vouch for its purity, using unsafePerformIO to bring it into the world of pure functions.

6.5 Related work

Aside from the vanilla foreign function interface used as the basis of our interface, there are several different, more modern, takes on interfacing purely functional languages with host language code. One common denominator is specialization: without exception, these implementations rely in large part on Modifications to the compiler or language itself, in contrast to our interface which makes some sacrifices in order to be implementable as a library, maximizing portability across host and Haskell implementations alike.

Idris: host-parametric FFI.

Idris is a dependently typed, Haskell-like language with backends for several host environments, JavaScript being one of them [2]. Like Haskell, Idris features monadic IO, but unlike Haskell, Idris’ IO monad is, in a sense its foreign function interface. IO computations are constructed from primitive building blocks, imported using a function not unlike our host function described in section 2, and parameterized over the target environment. This ensures that Idris code written specifically for a native environment is not accidentally called from code targeting JavaScript and vice versa.

Idris’ import function does not necessarily accept strings of foreign language code, but is parameterized over the target environment just like the IO monad; for JavaScript-targeting code, foreign code happens to be specified as strings, but could conceivably consist of something more complex, such as an embedded domain-specific language for building Idris-typed host language functions.

Fay: featureful but static.

Our interface was partially inspired by the foreign function interface of the Fay language, a “proper subset of Haskell that compiles to JavaScript” [7]. While the two are very similar in syntax, allowing users to import typed strings of host language code, Fay’s solution is highly specialized. The compiler takes a heavy hand in the marshalling and import functionality, parsing the host language code and performing certain substitutions on it. While marshalling of arbitrary types is available, this marshalling is not easily controllable by the user, but follows a sensible but fixed format determined by the compiler. This approach makes sense, as the interface is designed to support the Fay language and compiler alone, but differs from our work which aims to create a more generally applicable interface.

GHCJS: JavaScriptFFI.

The GHCJS Haskell-to-JavaScript compiler [13] utilizes the relatively recent JavaScriptFFI GHC extension, which has unfortunately been rarely described outside a GHCJS context, to the point of being conspicuously absent from even the GHC documentation. Much like Fay, this extension parses and performs substitutions over imported host language code to make imports slightly more flexible, allowing for importing arbitrary expressions rather than plain named functions. It also enables additional safety levels for foreign imports: safe, where bad input data is replaced by default values and foreign exceptions caught and marshalled into Haskell equivalents, and interruptible, which allows host language code to suspend execution indefinitely even though JavaScript is completely single threaded. This is accomplished by handing interruptible functions a continuation in addition to their usual arguments, to call with the foreign function’s “return value” as its argument when it is time for the foreign function to return and let the Haskell program resume execution.

The JavaScriptFFI extension preserves the regular FFI’s onerous restrictions on marshallable types however, and while while GHCJS comes with convenience functions to convert between these more complex types and the simple ones allowed through the FFI, marshaling is not performed automatically and functions in particular are cumbersome to push between Haskell and JavaScript.

UHC: the traditional FFI, on steroids for JavaScript.

The UHC Haskell compiler comes with a JavaScript backend as well, and matching higher-level extensions to its foreign function interface [6]. Like Fay, UHC provides automatic conversion of Haskell values to JavaScript objects, as well as importing arbitrary JavaScript expressions, with some parsing and wildcard expansion. Also like Fay, the JavaScript representation produced by this conversion is determined by the compiler, and is not user configurable. UHC does, however, provide several low level primitives for manipulating JavaScript objects from within Haskell, both destructively and in a purely functional manner.

Clean: mixing host and client language code.

The Clean language sports a foreign function interface which differs slightly from the rest of the interfaces discussed here. In Clean, the module system makes a difference between definition modules, where abstract types and functions are declared, and implementation modules, where implementations are given for the types and functions declared in the corresponding definition modules. Instead of using a special “foreign import” syntactic form, Clean allows developers to write system implementation modules: modules where the implementations of functions defined in a definition module may be written in a language other than Clean [16]. How-
ever, only primitive types may be passed to this foreign code and no guarantees, making higher-level interoperability cumbersome. Clean’s FFI is thus more flexible than the foreign function interface of GHC, allowing host and client language code to be mixed, but less so than the other interfaces discussed in this section due to its less expedient marshalling capabilities.

**Quasiquoting.**
Quasiquoting represent another, more radically different, approach to the problem of bridging with a host language [12]. Allowing for the inline inclusion of large snippets of foreign code with compile time parsing and type checking, quasi-quotes have a lot in common with our interface, even eclipsing it in power through anti-quotes, which allow the foreign code expressions to incorporate Haskell data provided that the proper marshalling has been implemented. Recent work by Manuel Chakravarty has extended the usefulness of quasi-quotes even further, automating large parts of the stub generation and marshalling required for using quasi-quoted host language code as a foreign function interface [4]. This usefulness comes at the price of a more involved implementation. Quasiquoting requires explicit compiler support in the form of compile time template metaprogramming as well as special extensions for running the quasiquoters themselves. In order to make full use of its compile time parsing and analysis capabilities an implementor also need to supply a parser for the quoted language.

7. CONCLUSIONS AND FUTURE WORK

**Future work.**
While our interface is designed for web-targeting Haskell dialects, extending its applicability is generally a venue worthy of further exploration.

As described in section 6.2 our interface has yet to be implemented for host languages other than JavaScript. Demonstrating that it is practically portable to at least one other host language would give additional weight to our claims of portability and improve the general applicability of the interface.

By combining two optimizations given in section 3, the restriction of our `safe_host` function to only accept statically known strings and the elimination of calls to `eval` for statically known strings, it is possible to remove the requirement that a potential host language support dynamic code evaluation. If all foreign imports are statically known, and we are able to eliminate `eval` calls for all statically known functions, it follows that we are able to eliminate all `eval` calls. While the actual implementation of this idea has yet to be worked out, guaranteeing the complete absence of `eval` from the generated host code would remove the restriction that our host language supports dynamic code evaluation at runtime, nearly making our interface implementable on recent versions of the Java Virtual Machine if not for the dynamic typing requirement. Investigating ways around this restriction and an implementation of our interface for the Java Virtual Machine, with the prerequisite Haskell-to-JVM compiler, would lend additional applicability to our interface.

Due to the hard requirement that our host language be garbage collected, our interface is not currently applicable in a C context. This is unfortunate, as C-based host environments are still by far the most common for Haskell programs. It may thus be worthwhile to investigate the compromises needed to lift the garbage collection requirement from potential host environments.

**Conclusions.**
We have presented the design and implementation of a novel, portable foreign function interface for web-targeting Haskell dialects. While designed for the web sphere, the given implementation is also applicable to a wide range of other high level target languages as well.

We have also given a number of optimizations, improving the performance and safety of our interface and lightening the restrictions placed on the host environment, and implemented our interface as a library for the Haste Haskell-to-JavaScript compiler. Finally, we have used this library to further extend our marshalling capabilities to cover functions and foreign exceptions, contrasted our approach with a variety of existing foreign function interfaces, and demonstrated that our library does not introduce excessive performance overhead compared to the vanilla FFI.

While our interface is currently not applicable to Haskell implementations targeting low level, C-like environments, it brings significant reductions in boilerplate code and complexity for users needing to interface their Haskell programs with their corresponding host environment in the space where it is applicable: web-targeting Haskell implementations.

8. ACKNOWLEDGEMENTS

This work has been partially funded by the Swedish Foundation for Strategic Research, under grant RAWFP. Many thanks to Koen Claessen, Emil Axelsson and Atze van der Ploeg for their valuable feedback and comments.
