12 **Abstract**

13 The effect of cooling rate after solution treatment on the initial structure of concentrated binary
14 Fe-Cr alloys and the effect of the initial structure on phase separation during subsequent aging
15 has been investigated. The nano-scale compositional fluctuations in the bulk of the alloys are
16 studied using small-angle neutron scattering and the results are compared with simulations using
17 the Cahn-Hilliard-Cook (CHC) model. The alloys investigated represent different mechanisms of
18 phase separation and at higher Cr content, when spinodal decomposition (SD) is favored, the
19 initial Cr compositional fluctuations due to slow cooling after solution treatment reduce the
20 kinetics of phase decomposition, whereas, at lower Cr composition when nucleation and growth
21 is favored, the kinetics of phase decomposition is more rapid. Regardless of the nominal Cr
22 composition of the alloy, the phase decomposition after extended aging up to 300 h at 748 K is
23 always larger for the more non-random initial structure. The CHC modeling of the cooling
24 process and subsequent initial aging (below 10 h) is in reasonable qualitative agreement with the
25 experimental results for the Fe-40 wt.% Cr alloy decomposing via SD. However, the modeling
26 approach must be refined for accurate quantitative modeling of the full SD process, including
27 coarsening.

28 **Key words:** Phase separation, spinodal decomposition, cooling rate, small-angle neutron
29 scattering, stainless steel

30 **1. Introduction**

31 The body-centered cubic (bcc) and tetragonal (bct) phases in Fe-Cr based alloys, i.e. stainless
32 steels, will experience phase separation (PS) when they are heat treated within the miscibility
33 gap. Hence, the assumed initially random alloy decomposes into Fe-rich (α) and Cr-rich (α')
34 regions, causing the so-called “475 °C embrittlement” with increased hardness and decreased
35 toughness of the alloy. Since these materials are promising candidates in e.g., future designs of
36 nuclear power plants [1,2], structural integrity is clearly important and the “475 °C
37 embrittlement” must be avoided. Currently there are significant research efforts on-going to
38 study the mechanisms controlling the phase decomposition under different conditions, and to
39 find ways of mitigating the embrittlement.

40 It is known that the bcc/bct phase in solution treated Fe-Cr alloys is not always a random alloy.
41 Instead, compositional fluctuations of Cr may occur already during the solution treatment and
42 depends on the solution treatment temperature as well as the cooling rate after solution treatment
43 [3–11]. Huston et al. [3] simulated spinodal decomposition (SD) during continuous cooling,
44 using the linearized Cahn-Hilliard model. They suggested a critical cooling rate and that by
45 exceeding the critical cooling rate SD will be avoided, but if the cooling rate is slower than the
46 critical rate, decomposition will occur. In their simulations, slower cooling rates led to more
47 pronounced decomposition. Carmesin et al. [4] further studied SD during continuous cooling by
48 performing simulations using: the linearized Cahn-Hilliard model specifically incorporating
49 thermal fluctuations, i.e. the Cook extension, the non-linear Langer-Bar-on-Miller theory (LBM),
50 and the Monte Carlo technique. Their results indicated that PS evolves faster for samples cooled
51 with finite rates rather than in an instantaneous process. Later experimental work have also
52 confirmed that PS can occur in the ferrite during cooling from the solution treatment temperature
53 in both ferritic and duplex stainless steels [5,6]. The hardness of ferrite in unaged duplex
54 stainless steels was evaluated to be greater for samples cooled with lower rates and this was
55 attributed to more severe PS at lower cooling rates [12]. Atom probe tomography measurements
56 verified that the amplitude of Cr compositional fluctuations was larger for unaged samples that
57 were cooled at slower rates, and that this initial difference was also present after aging [13]. As
58 mentioned, it is also known that the solution treatment temperature affects the initial structure.
59 Vintaykin et al. [7] and LaSalle and Schwartz [8] have shown that solution treatments of Fe-Cr
60 alloys at different temperatures above the miscibility gap lead to different small-angle neutron
61 scattering (SANS) results, indicating different microstructures. Moreover, the kinetics of SD was
62 found to depend on this initial microstructure, and a higher solution treatment temperature
63 resulted in slower kinetics of SD. Mirebeau et al. [14,15] studied the short range order of Fe-Cr
64 alloys thermally treated at 703 K by diffuse neutron scattering [16]. They showed that Fe-Cr is
65 prone to ordering when the Cr content is below 0.107, while clustering occurs when the Cr
66 content is above 0.107. Theoretical calculations predicted a similar tendency for the short-range
67 order (SRO) parameter with a change of sign with increasing Cr content [17–21]. The tendency
68 of Cr clustering in Fe-Cr alloys with higher Cr contents has also been shown by Zhou et al.
69 [10,11,22].

70 As portrayed in the literature survey above, the initial structure is an important factor when it
71 comes to predicting the evolution of PS during aging. The cooling rate after solution treatment
72 seems to affect the initial structure and it is therefore important to have a greater understanding
73 of the effect of cooling rates, and also its alloying dependence in continuous cooling
74 experiments. Furthermore, studying the aging behavior of samples cooled in different ways
75 might improve our understanding of the effect of the initial structure on PS. Thus, in the present
76 work we conducted a systematic investigation of the effect of cooling rate after solution
77 treatment on the initial structure of Fe-Cr alloys and, furthermore, the effect of the initial
78 structure on PS during subsequent aging. The initial structure after solution treatment and the
79 kinetics of PS are investigated using small-angle neutron scattering (SANS). SANS theories
80 consider the structure factor which can be directly linked to Cahn-Hilliard (CH) model.
81 Therefore, the experimental results are compared to simulations using the linearized Cahn-
82 Hilliard-Cook (CHC) model.

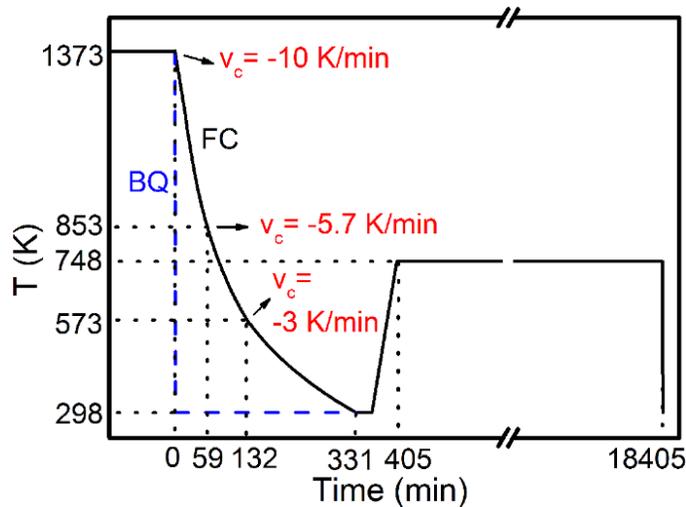

83 **2. Methodology**

84 Binary Fe-Cr alloys with chemical compositions listed in Table 1 were prepared by vacuum arc
85 melting. Fe-20Cr and Fe-40Cr alloys were cut into around $10 \times 10 \times 1.7$ mm³ samples, whereas Fe-
86 25Cr and Fe-35Cr alloys were cut into around $5 \times 5 \times 1.7$ mm³ samples. Thereafter, all samples
87 were solution treated at 1373 K for 2 h in a slight overpressure of pure argon. The cooling after

88 solution treatment was performed in two ways: i) furnace cooling (FC) or ii) quenching in brine
 89 (BQ). The entire cooling process from solution treatment temperature to room temperature for
 90 FC samples was $t_{FC}=5.5$ h and the cooling through the temperature interval where the PS kinetics
 91 is reasonably fast, i.e. 573-853 K [23] was 73 min giving an average cooling rate of ~ 4 K/min
 92 (the cooling rate is 5.7 K/min at 853 K and 3 K/min at 573 K). Both FC and BQ samples were
 93 then aged at 748 K for up to 300 h as detailed in Table 1. The thermal cycles are also
 94 schematically shown in Fig. 1. For simplicity, the sample notation from hereon is: cooling
 95 method, alloy composition and aging time. For example, FC20Cr1 represents alloy Fe-20Cr
 96 cooled by FC and aged at 748 K for 1 h. The unaged samples are represented by zero aging time.

Table 1. Chemical compositions of Fe-Cr alloys (wt.%) and the isothermal aging times at 748 K. FC and BQ represent furnace cooling and quenching in brine, respectively.

Alloy	Cr	C	Si	Mn	S	P	N	Ni	Fe	Cooling process	Aging time (h)
20Cr	19.8	0.002	0.03	0.11	0.004	0.005	0.008	--	Bal.	FC	0, 1, 10, 300
										BQ	0, 1, 10, 300
25Cr	25.28	0.002	0.09	0.005	0.006	0.004	0.009	0.03	Bal.	FC	0, 300
										BQ	0, 300
35Cr	36.10	0.005	0.09	0.006	0.005	0.005	0.008	0.02	Bal.	FC	0, 300
										BQ	0, 300
40Cr	41.09	0.007	0.105	0.114	0.006	0.006	0.006	0.02	Bal.	FC	0, 1, 10, 300
										BQ	0, 1, 10, 300

97
 98 Fig. 1 Schematic diagram of the heat treatment cycles imposed on the different samples (v_c is the
 99 cooling rate).

100 The samples were ground and polished by sand papers (up to P1200 grit) to 1.5 mm thickness in
 101 order to remove the oxide layer prior to the neutron experiments. The LOQ diffractometer at the
 102 ISIS Pulsed Neutron Source (Oxfordshire, UK) was used for SANS measurements. This
 103 instrument uses the time-of-flight technique, coupled with a broad range of incident neutron
 104 wavelengths and two position-sensitive detectors, a multi-wire proportional gas counter and an
 105 annular scintillator area detector [24], to provide a simultaneous scattering vector range of 0.008

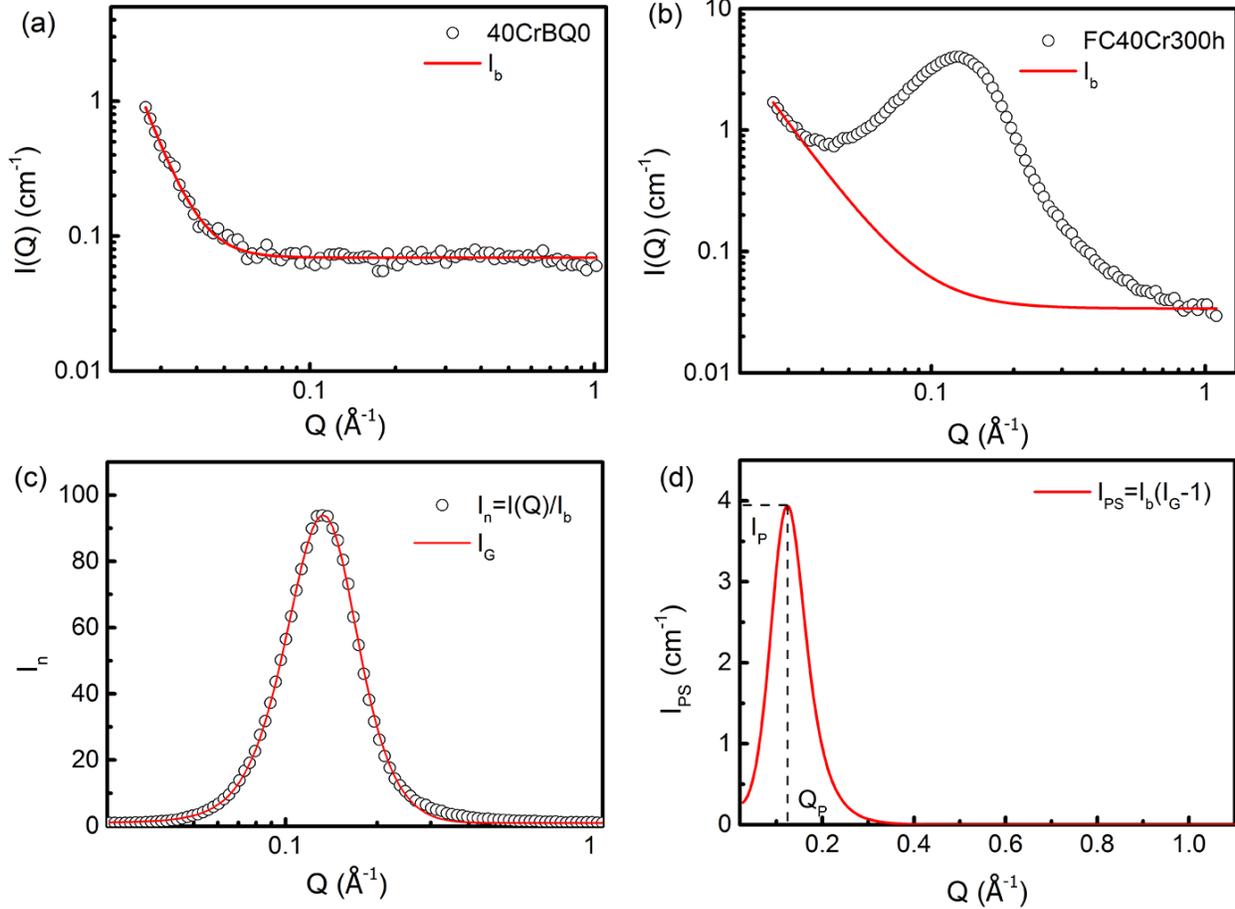

106 $\leq Q \leq 1.4 \text{ \AA}^{-1}$ (where $Q = 4\pi\sin\theta/\lambda$, 2θ is the scattering angle, and λ is the wavelength). The
 107 neutron beam was collimated to a diameter of 4 mm and data were collected for 2 h per sample
 108 at room temperature. The raw SANS data were corrected for the efficiency and spatial linearity
 109 of the detectors, instrumental background, sample transmission and illuminated volume using the
 110 Mantid framework (version 3.2.1) [25,26], to yield the macroscopic coherent differential
 111 scattering cross section ($\partial\Sigma(Q)/\partial\Omega$) as a function of Q . This was then placed onto an absolute
 112 scale using the scattering from a standard sample (a partially-deuterated polymer blend of known
 113 molecular weight) [27]. $\partial\Sigma(Q)/\partial\Omega$, colloquially called the intensity, $I(Q)$, is directly related to
 114 both the nuclear and magnetic nanostructure of the alloys. But in this study, the nuclear and
 115 magnetic scattering were not separated (using a saturating magnetic field) since the prior reports
 116 [8,28–30] have claimed that the nuclear and magnetic scattering have a similar Q -dependence at
 117 $Q > 0.05 \text{ \AA}^{-1}$ for the early stage of phase separation. The magnetic scattering from magnetic
 118 domains mainly contributes to $I(Q)$ at low- Q ($Q < 0.05 \text{ \AA}^{-1}$), and it will not interfere with the
 119 length-scale of interest in this study, i.e. the length-scale of Cr fluctuations, when $I(Q)$ is
 120 averaged over all directions [8,28–30].

121 In the two-phase model, where the second phase (precipitate) is embedded in the matrix,
 122 assuming the precipitates are identical and the concentration of the precipitates is high, $I(Q)$ can
 123 be generally expressed as [31–33]

$$124 \quad I(Q) = N_P V_P^2 (\Delta\delta)^2 P(Q) S(Q) \quad (1)$$

125 where N_P is the number density of precipitates, V_P is the volume of a precipitate (such that
 126 $N_P V_P = \Phi_P$, the volume fraction), and $\Delta\delta = \rho_p - \rho_m$ is the difference in neutron scattering length
 127 density between the precipitate (ρ_p) and matrix (ρ_m). $(\Delta\delta)^2$ is called the scattering contrast which
 128 is critical to distinguish the precipitate from the matrix. It also indicates the composition
 129 difference between the precipitate and matrix since ρ_p and ρ_m are determined by the respective
 130 phase compositions [33]. $P(Q)$ is the single-particle form factor which depends on the shape and
 131 size of the considered precipitate domain [34]. $S(Q)$, the structure factor, is the Fourier transform
 132 of the static pair correlation function, which describes the correlation between precipitates. When
 133 the concentration of precipitates is low, $S(Q) \rightarrow 1$, meaning the inter-precipitate correlations can
 134 be neglected and the scattering is dominated by $P(Q)$ [31,32]. However, when the concentration
 135 of precipitates is high, $S(Q)$ endows $I(Q)$ with an interference peak that becomes more
 136 pronounced as the correlations become more definitive. The position (Q_P) of this interference
 137 peak represents an average characteristic length scale (d), through $d = 2\pi/Q_P$ [33]. In this study,
 138 Fe-20Cr decomposes via a non-classical nucleation and growth (NG) mechanism to give a
 139 structure consisting of α' particles and α matrix, d is the average distance between α' domains
 140 [23,35]. Fe-25Cr is in the transition region between NG and SD and, hence, a structure with both
 141 particle and interconnected features could be present [23,36,37]. The alloy composition is in the
 142 NG region according to available thermodynamic descriptions (at 748 K, the spinodal limit in the
 143 Fe-rich side is at 29.7 at.% [37] and 35.7 at.% [38]). It is therefore believed that the Fe-25Cr
 144 alloy mainly decompose via NG. On the other hand, Fe-35Cr and Fe-40Cr mainly decompose via
 145 SD leading to an interconnected structure [37]. In these alloys d is the average wavelength
 146 characterizing the spinodal structure. The above description also implies that the peak intensity
 147 (I_P) is an indicator of the evolution of the nanostructures as has been previously shown
 148 [30,39,40]. Q_P and I_P were determined from the SANS patterns as described by Xu et al. [40]
 149 using the similar method as in [30]. To accomplish this, the scattering due to PS was isolated by
 150 subtracting the background signal as shown in Fig. 2. In this study, the $I(Q)$ of BQ unaged
 151 samples was treated as that of homogeneous samples without decomposition due to Q -
 152 independent scattering beyond $Q = 0.1 \text{ \AA}^{-1}$. As shown in Fig. 2a, the SANS of BQ unaged samples

153 can be fitted by a power law function. Therefore, the background of different conditions were
 154 fitted in the same way, namely, by a power law function of the form, $I_b=x+yQ^z$, see Fig. 2b. Then
 155 $I(Q)$ was normalized by I_b such that, $I_n=I(Q)/I_b$ and the plot of I_n vs. $\log Q$ was fitted by a
 156 Gaussian function, I_G (Fig. 2c). Finally, the scattering function for PS, I_{PS} , was separated as
 157 $I_{PS}=I_b(I_G-1)$ (Fig. 2d). Since $I_G \geq 1$, these procedures ensure that all the data have positive
 158 intensities after subtracting the background.

159
 160 Fig. 2 Schematic of fitting the scattering functions and quantifying the PS: (a) fitting of data of
 161 BQ unaged samples; (b) fitting of background, I_b , by a power law function of the form, $I_b=x+yQ^z$,
 162 (c) fitting of the normalized signal, $I_n=I(Q)/I_b$, by a Gaussian function, I_G ; (d) the scattering
 163 function for phase separation, I_{PS} , was separated as $I_{PS}=I_b(I_G-1)$. Q_P and I_P are the peak position
 164 and peak intensity.

165 The PS during cooling and subsequent isothermal aging at 748 K was simulated for BQ40Cr and
 166 FC40Cr alloys using the CHC model. The structure factor $S(Q,t)$ in the CHC framework can be
 167 written as [8,41]:

$$168 \quad S(Q,t) = \frac{RT}{f'' + 2\kappa Q^2} + \left[S_0 - \frac{RT}{f'' + 2\kappa Q^2} \right] \times \exp\left\{ -2M(f'' + 2\kappa Q^2)Q^2 t \right\} \quad (2)$$

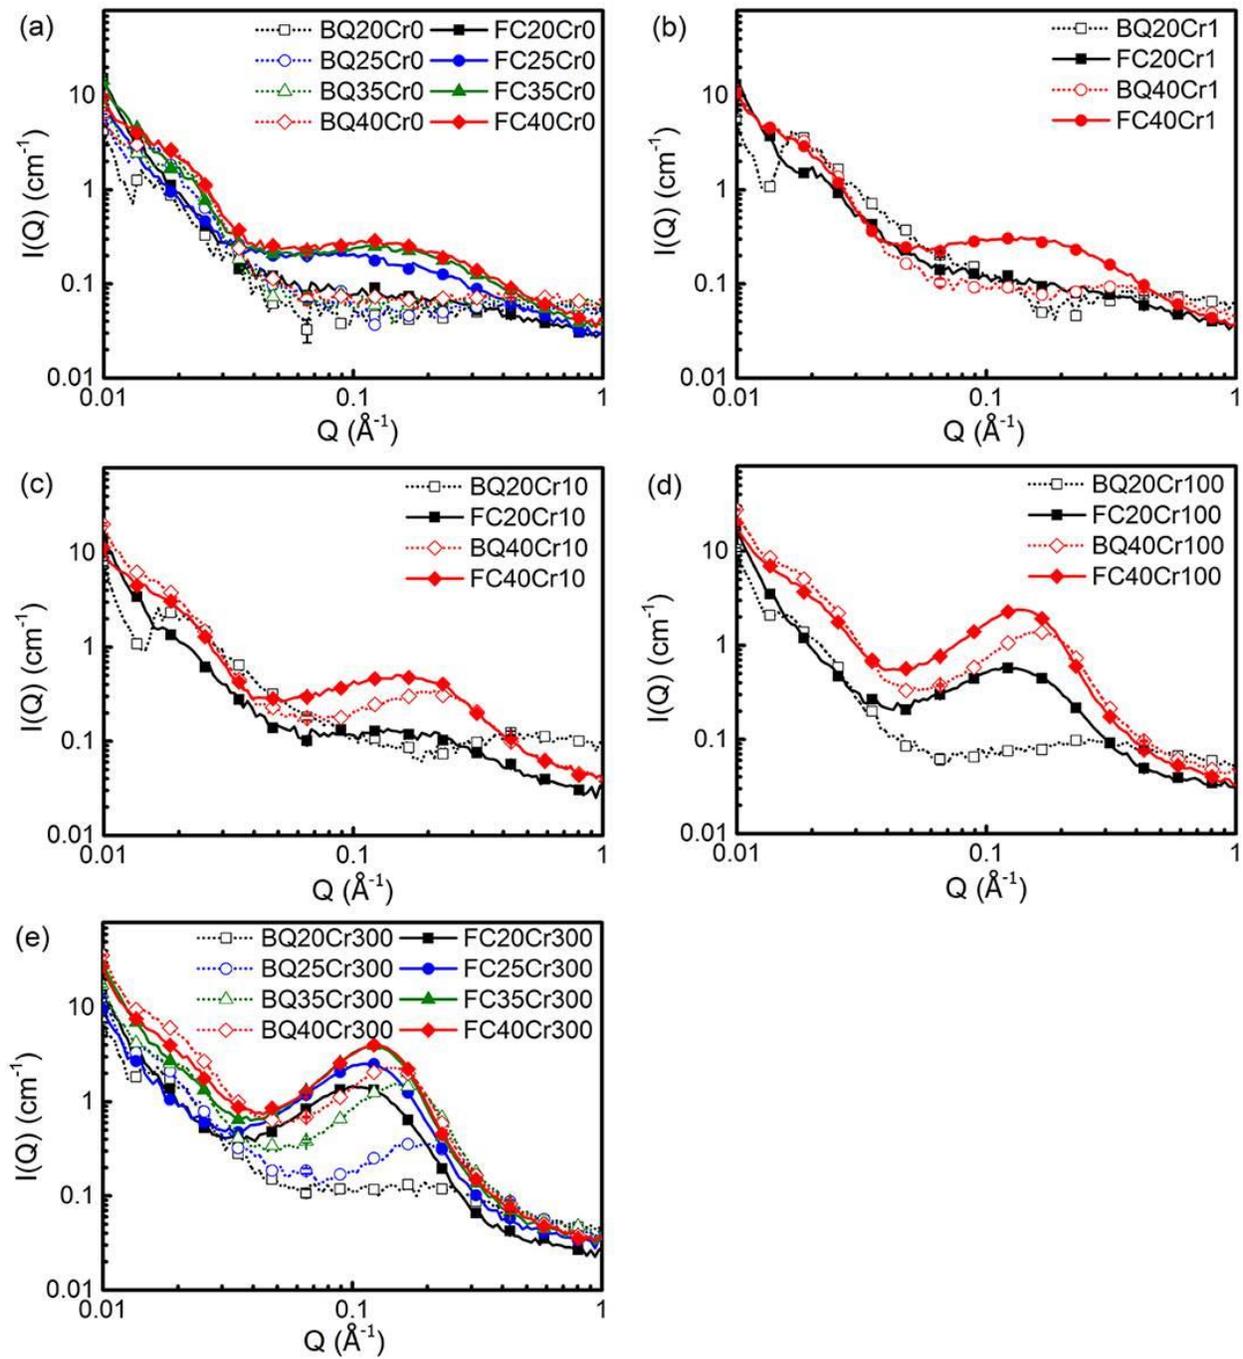

169 where $S_0=S(Q,t=0)$ is the initial structure factor, f'' is the second derivative of the molar Gibbs
 170 energy with respect to the mole fraction of Cr taken from the Thermo-Calc Software TCFE8
 171 Steels/Fe-alloys database version 8 (the binodal solubility limits at 748 K are at 15.7 and 88.3
 172 at.% Cr, and f'' is -7.35×10^3 J/mol at 748 K) [42], κ is the gradient energy coefficient:
 173 $\kappa = a^2 L^0_{CrFe}/2$, a is the interaction distance taken to be 2.5 Å and L^0_{CrFe} is the regular solution

174 parameter: $L^0_{CrFe}=20500-9.68T$ [38]. R and T are the gas constant and absolute temperature,
175 respectively. M is the atomic mobility: $M=x_0(1-x_0)[x_0M_{Fe}+(1-x_0)M_{Cr}]$, where x_0 is the average
176 molar content of Cr, and M_{Fe} and M_{Cr} are the atomic mobilities for Cr and Fe, respectively. The
177 atomic mobilities were taken from the Thermo-Calc Software MOBFE2 Steels/Fe-alloys
178 database version 2 [43]. For the BQ condition $S_0=1$, assuming that no PS takes place during the
179 quenching. On the other hand, for the FC condition a function
180 ($T=1377-13.19t+8.64\times 10^{-2}t^2-3.29\times 10^{-4}t^3+6.46\times 10^{-7}t^4-5.10\times 10^{-10}t^5$, where T is temperature,
181 t is time) was fitted to the experimental cooling curve in Fig. 1. This cooling cycle was then used
182 to calculate the structure factor according to eq. (2) after discretizing the cooling cycle in discrete
183 temperature steps. A similar procedure was suggested by Carmesin et al. [4]. The furnace
184 cooling started at 1377 K and ended at room temperature. For each new temperature step the
185 structure factor S calculated in the prior step was set to S_0 . In this way the effect of a finite
186 cooling rate on the PS could be simulated. The final structure factor at room temperature was
187 then used as S_0 in eq. (2) for the isothermal aging at 748 K assuming that the heating from room
188 temperature to the aging temperature was so rapid that no additional PS could take place.

189

190 3. Results

191 Fig.3 shows the SANS data of Fe-Cr alloys subjected to different cooling rates after solution
192 treatment, and then aging for different times at 748 K. As can be seen in Fig. 3a, the data of
193 unaged samples from the same alloys are significantly different when comparing the two
194 different conditions BQ and FC. After a steady decrease in intensity in the low- Q range, the
195 SANS data of the BQ samples level off beyond $Q=0.1 \text{ \AA}^{-1}$, i.e. no nano-scale structure is evident.
196 However, the FC unaged samples do show a nano-scale structure with a broad correlation peak
197 appearing in the scattering data. All scattering data of the aged samples have this type of shape
198 and it should be interpreted as PS in both unaged FC and aged samples. The slight convex
199 curvature of the scattering data at low- Q is most likely due to some oxide inclusions that were
200 identified using scanning electron microscopy, but since the length-scale is not interfering with
201 the PS it is simply neglected from hereon as well as in the background fitting.

202

203 Fig. 3 SANS data of Fe-Cr cooled at different rates: (a) unaged, (b) 1 h aging, (c) 10 h aging, (d)
 204 100 h aging and (e) 300 h aging. Note that the error bar is quite small and covered by the
 205 symbols.

206 The quantification of d and I_P for the different conditions is tabulated in Table 2 and it can be
 207 seen that FC unaged samples have relatively large I_P , which means that the samples have
 208 decomposed, and the d values show the length-scale of the decomposition. The values of d and I_P
 209 for FC unaged samples are comparable to, or even larger than, those of BQ samples aged for 10
 210 h from the same alloys, though the entire FC process time is shorter than 10 h. These results
 211 indicate that the size of α' and the compositional fluctuations in the unaged FC samples are
 212 already quite well developed.

Table 2 Characteristic distance, d , and peak intensity, I_P , of different alloy compositions and aging conditions.

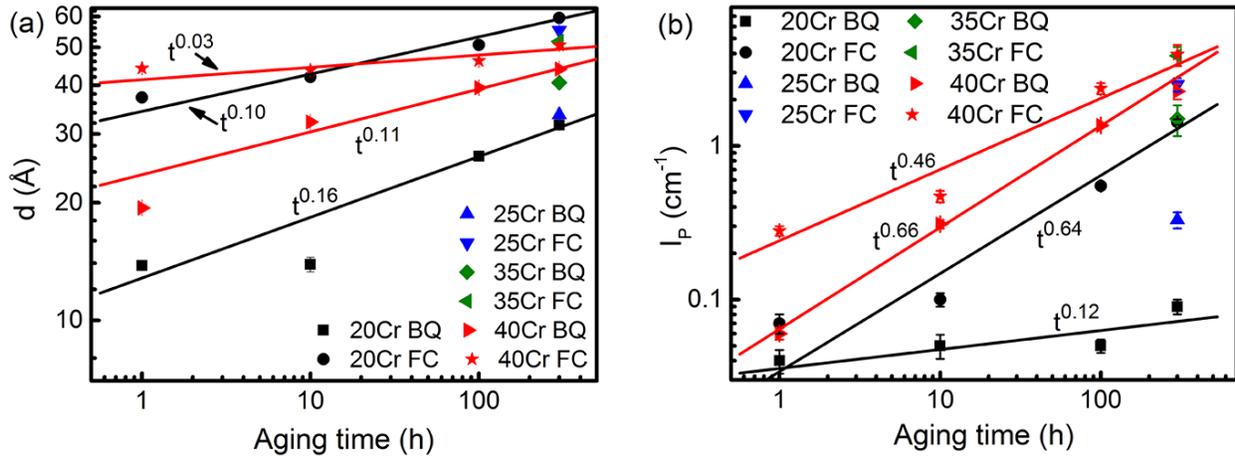

Alloy conditions	d (Å)	I_P (cm ⁻¹)	Alloy conditions	d (Å)	I_P (cm ⁻¹)
BQ20Cr1	13.8±0.4	0.04±0.007	BQ35Cr300	40.6±0.2	1.50±0.34

213

214 For aged samples, the peak in the SANS data for FC samples is more pronounced than for the
 215 BQ samples for the same alloy, exposed to the same aging treatment (Fig. 3 and Table 2). The
 216 values of d and I_P of FC samples are larger than those of BQ samples. This indicates that samples
 217 with slower cooling rates have larger characteristic distances and composition amplitudes and/or
 218 volume fraction of the precipitate. It should be noted that the difference caused by the applied
 219 cooling process after solution treatment is still large after 300 h aging, though the FC process
 220 time is rather short in comparison with the aging time of 300 h. For the same thermal treatment,
 221 alloys with higher Cr content generally have larger d , and I_P with the exception for d of the FC
 222 samples that have been aged for 300 h. These samples have rather similar d .

223 Theoretical models have illustrated that the evolution of Q_P , and therefore d , and I_P with aging
 224 time can be described by power laws, namely, $Q_P \propto t^{-a}$, $d \propto t^a$, and $I_P \propto t^b$ [44–46]. As shown
 225 in Fig. 4a and b, a for BQ 20Cr and 40Cr is 0.16 and 0.10, and for FC20Cr and FC40Cr it is 0.10
 226 and 0.03, respectively. d of FC40Cr does not change much within the aging period, while d of
 227 other conditions has an obvious increase. b for BQ20Cr and BQ40Cr is 0.12 and 0.66, and for
 228 FC20Cr and FC40Cr it is 0.64 and 0.46, respectively. Hence, the kinetics of PS during aging is
 229 slower for FC40Cr than for BQ40Cr according to both a and b . This is consistent with the results
 230 of the Monte Carlo simulations by Hyde et al. [47]. They found that slower cooling rates result in
 231 smaller a during aging for a simple A-B alloy with cubic lattice. The above a values also indicate
 232 that the decomposition is still in the early stage and that they have not reached the coarsening
 233 stage where $d \propto t^{1/3}$ as shown in [36] based on the theories of Lifshitz-Slyozov-Wagner [48,49]

234 and Huse [50]. On the other hand, for Fe-20Cr, d of the FC samples increases slower with aging
 235 time compared to that of the BQ samples, whereas, I_P shows the opposite trend. d and I_P of
 236 FC20Cr and BQ20Cr are significantly different after 300 h aging. By contrast, d and I_P of
 237 FC40Cr and BQ40Cr almost converge after 300 h aging. The differences between values for
 238 BQ35Cr and FC35Cr are also smaller than that of Fe-25Cr, see Fig. 4 and Table 2. Though the
 239 effect of the cooling rate should eventually be eliminated for all alloys, the differences fade faster
 240 during aging for alloys with higher Cr content.

241
 242 Fig. 4 Values of (a) d and (b) I_P . The values of Fe-20Cr and Fe-40Cr alloys are fitted by power
 243 laws using the linear regression approach. The linear regression coefficient R^2 for the fitting of d
 244 is: $R^2(20\text{Cr BQ})=0.86$, $R^2(20\text{Cr FC})=0.91$, $R^2(40\text{Cr BQ})=0.65$, $R^2(40\text{Cr FC})=0.99$, and for the
 245 fitting of I_P is: $R^2(20\text{Cr BQ})=0.93$, $R^2(20\text{Cr FC})=0.99$, $R^2(40\text{Cr BQ})=0.93$, $R^2(40\text{Cr FC})=0.94$.

246
 247 The simulated structure factor at 748 K aging for the BQ condition can be seen in Fig. 5a and d.
 248 Here the atomic mobility M in eq. (2) was adjusted to $3.1 \times 10^{-27} \text{ m}^2\text{mol/Js}$ so the characteristic
 249 distance d for $t=1$ h between the experiments ($d=19.4 \text{ \AA}$ from Table 2) and simulations ($d=19.8$
 250 \AA) was as close as possible. This mobility was then used for the remaining simulations of aging
 251 at 748 K for the BQ and FC conditions. The simulated time was restricted to $t=10$ h since longer
 252 times resulted in an unrealistically large structure factor. This is not surprising since the
 253 linearized CHC should be valid only for early stages of PS. Comparing the characteristic
 254 distance from experiments for BQ40Cr10 ($d=32.2 \text{ \AA}$) and simulations ($d=27.8 \text{ \AA}$), the agreement
 255 is considered to be reasonable.

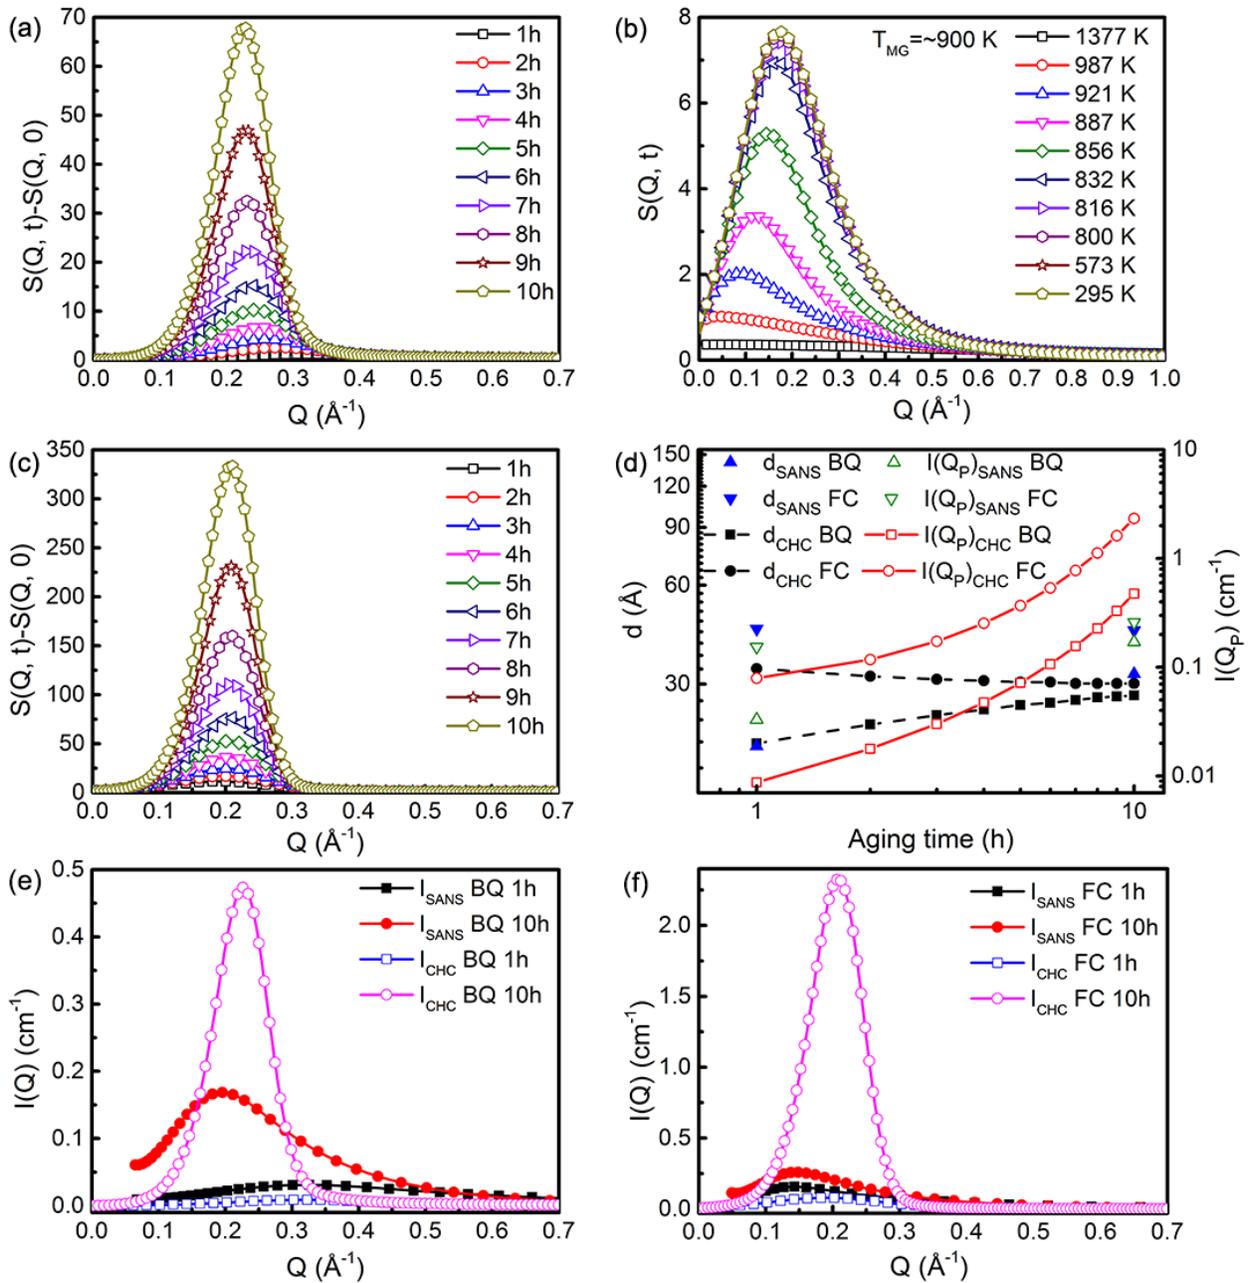

256 The simulated structure factors during FC can be seen in Fig. 5b. Outside the miscibility gap
 257 [38], the structure factor changes only slightly but once inside the miscibility gap and inside the
 258 spinodal, a clear peak in the structure factors develops, i.e. PS occurs during cooling, and it has a
 259 distinct characteristic distance, see Fig. 5b. As the temperature is decreased, d becomes smaller
 260 and the peak intensity, $S(Q_P, t)$, becomes larger. This is consistent with the results from Carmesin
 261 et al. [4]. When the temperature is lowered below about 700 K, d and $S(Q_P, t)$ remain almost the
 262 same.

263 The effect of a finite cooling rate on the microstructure evolution during aging at 748 K is clearly
 264 seen in Fig. 5c and d, where the characteristic distance starts from a much higher value compared
 265 to the BQ condition. Although the absolute values of d are not in perfect agreement with
 266 experiments the trend is qualitatively captured by the CHC model. From Fig. 5d, it can be seen
 267 that d of FC is almost unchanged with aging time, while d of BQ increases with aging time. In
 268 addition, the coherent differential cross section, $I(Q)_{CHC}$, derived from $S(Q, t)$ is presented

269 together with the experimental results in Fig. 5e and f. The maximum value, $I(Q_P)_{CHC}$, of
270 $I(Q)_{CHC}$, is also shown for comparison with experimental values in Fig. 5d. $I(Q)_{CHC}$ is calculated
271 in the same way as in [8,9]:

$$272 \quad I(Q)_{CHC} = N_v x_{Cr} (1 - x_{Cr}) (b_{Cr} - b_{Fe})^2 S(Q, t) \quad (3)$$

273 where $N_v = 8.427 \times 10^{22} \text{ cm}^{-3}$ is the atomic number density of Fe-40Cr, $x_{Cr} = 42.76 \text{ at. \%}$ is the
274 atomic fraction of Cr, $b_{Cr} = 3.635 \times 10^{-13} \text{ cm}$, $b_{Fe} = 9.45 \times 10^{-13} \text{ cm}$ [51] are the scattering length of Cr
275 and Fe, respectively. $I(Q)_{CHC}$ corresponds to the nuclear scattering. LaSalle and Schwartz [8]
276 reported that the nuclear and magnetic scattering of Fe-Cr have the identical Q dependence at the
277 early stage of SD and the ratio of the nuclear scattering intensity to the total intensity is around
278 0.55 for Fe-32%Cr [28]. Therefore, I_{PS} from SANS is multiplied by 0.55 and shown as I_{SANS} in
279 Fig. 5e and f, and the maximum value of I_{SANS} is shown as $I(Q_P)_{SANS}$ in Fig. 5d. $I(Q_P)_{CHC}$ and
280 $I(Q_P)_{SANS}$ both show the trend that the difference in the initial structure fade during aging, but the
281 absolute values are somewhat different and, also, $I(Q_P)_{CHC}$ implies faster kinetics. The agreement
282 between I_{CHC} and I_{SANS} is lower after 10 h aging as compared to 1 h aging, see Fig. 5e and f. The
283 modelling results indicate that the kinetics of PS is faster for the BQ conditions than for the FC
284 conditions, which is in good agreement with the SANS results. It should be pointed out that the
285 excellent fitting of the SANS data by the CHC model in [8,9] is due to that f'' , M and κ were used
286 as fitting parameters, varying for each aging condition, instead of taking physically assessed
287 quantities.

288

289 Fig. 5 Evolution of the structure factor, $S(Q,t)$, of Fe-40Cr simulated by the linearized CHC
 290 model: (a) BQ from 1377 K to room temperature followed by aging at 748 K for different times,
 291 (b) FC from 1377 K to room temperature (the temperature of the miscibility gap, $T_{MG} \sim 900$ K
 292 [38]), (c) aging of FC at 748 K for different times, (d) comparison of the evolution of d and $I(Q_P)$
 293 during aging between CHC modeling and SANS, the intensity from SANS, I_{SANS} , and linearized
 294 CHC model, I_{CHC} , for (e) BQ conditions and (f) FC conditions.

295

296 4. Discussion

297

298 The experimental results presented in the present work show the effect of different cooling rates
 299 on the subsequent PS during aging of binary Fe-Cr alloys with different compositions. It is clear
 300 that the effect of the cooling rate is composition dependent and that slow cooling, that could arise

301 when thicker gauge sections are cooled after manufacturing, will lead to PS during the cooling
302 process. This difference in the initial structure will then affect the subsequent aging kinetics and
303 it was found that the PS kinetics will be slower for slowly cooled samples when the nominal Cr
304 composition is 40 wt.%, whereas it will be faster for samples with a nominal Cr composition of
305 20 wt.%. This difference in PS kinetics is most likely due to the difference in PS mechanisms for
306 different Cr compositions. Alloys with a low Cr content (e.g. 20 wt.%) are believed to
307 decompose via NG and during slow cooling the initial nuclei will form, and these will grow and
308 coarsen during the isothermal aging at 748 K. The process at 748 K is then mainly diffusion-
309 controlled and comparing with the BQ samples where nucleation, growth and coarsening of the
310 particles is a concurrent process it is reasonable to suggest that the FC samples would experience
311 more rapid PS kinetics.

312 On the other hand, in alloys with a high Cr content (e.g. 40 wt.% Cr), which are believed to
313 decompose via SD, the slow cooling will lead to the development of sinusoidal waves of a longer
314 dominant wavelength since it depends on the critical wavelength, which increases with
315 increasing temperature. In contrast, the BQ samples will have a shorter dominant wavelength
316 during the aging since the critical wavelength at 748 K is smaller. Since SD is diffusion-
317 controlled it is reasonable to assume that the PS kinetics would be slower for the longer
318 wavelength structure due to the longer diffusion distance, i.e. this is most likely why the PS is
319 slower for the FC than for the BQ initial samples when the Cr content of the alloy is 40 wt.%.

320 Comparing the experimental results with the CHC modeling results for the Fe-40Cr alloy, it is
321 found that the model predictions can qualitatively capture the difference of the initial structures
322 between BQ and FC as well as its effect on the aging kinetics in the early stage of SD. The early
323 stage of SD can here be identified as aging at 748 K for less than 10 h, since already at 10 h, the
324 exponential evolution of the structure factor intensity is starting to shoot-off and will become
325 unreasonable, and in poor agreement with the experimental results. It should be noted that in
326 practice the interesting time frames at 748 K are in the order of 10 h. The mechanical properties
327 of the alloys will already then be affected and it has been shown in e.g. [52,53] that the impact
328 toughness of these types of model alloys may be very low after aging for 10 h at 748 K and 773
329 K, in that case. Though the trend was predicted by the modeling, I_{CHC} has a much higher peak
330 intensity than I_{SANS} for the 10 h aging condition in Fig. 5e and f. This may be attributed to the
331 linearization of the Cahn-Hilliard model, which includes the use of a constant M and a constant
332 f'' . This is a rather crude assumption and will break down for long aging times. Here M was
333 derived for BQ40Cr1 and remained the same for other conditions in the simulations since there is
334 a lack of an accurate description of the composition dependent M . Better descriptions of M
335 should be pursued, which was also pointed out by Nastar [54] in the comparison between CH
336 and Self-Consistent Mean Field theories. Moreover, the driving force for SD should be different
337 at different stages due to varying composition gradients. Hence, f'' should differ at different
338 stages of SD too. However, this is hard to handle in the linearized CHC model. More realistic
339 modeling predictions of a larger part of the PS process would be highly desirable. It should be
340 possible to move in that direction by implementing the non-linearized Cahn-Hilliard model and
341 considering composition dependent M as well as changing f'' . Moreover, it is necessary to look
342 more in detail on κ , because this term is controlling the sharpness of the interfaces of the
343 decomposing nano-structure.

344 It should, however, be emphasized that there are additional factors connected to the initial
345 structure that will affect the PS aging kinetics. Cr clustering that arises due to the short-range
346 order tendency above the miscibility gap [10,14,15,22,55–57] is one such factor and it cannot be
347 fully handled within a continuum approach such as the Cahn-Hilliard model. This effect is likely
348 to be a contributing factor to the deviation between I_{CHC} and I_{SANS} in Fig. 5f. However, it has

349 been found that, at present, this effect seems to be difficult to handle even with atomistic
350 simulations [11]. Further work on the modeling of the effect of the initial structure on the PS
351 kinetics is therefore necessary to find a viable modeling route.

352

353 **5. Conclusions**

354 In the present work it is found that the cooling process after solution treatment of Fe-Cr alloys
355 has a significant effect on the structure, and further, this structure will significantly affect the
356 phase separation (PS) evolution during subsequent aging at 748 K. The alloys investigated
357 represent different mechanisms of PS and at higher Cr content, when spinodal decomposition
358 (SD) is favored, the initial Cr compositional fluctuations due to slow cooling after solution
359 treatment reduce the kinetics of phase decomposition, whereas, at lower Cr composition when
360 nucleation and growth (NG) is favored, the kinetics of phase decomposition is more rapid.
361 Regardless of the nominal Cr composition of the alloy, the phase decomposition after extended
362 aging up to 300 h at 748 K is always larger for the more non-random initial structure. The Cahn-
363 Hilliard-Cook modeling of the cooling process and subsequent initial aging (up to about 10 h) is
364 in reasonable qualitative agreement with the experimental results for the Fe-40 wt.% Cr alloy
365 decomposing via SD. However, the modeling approach must be refined to enable accurate
366 quantitative continuum modeling of the full SD process, including coarsening. Furthermore, the
367 local atomic arrangement during the whole thermal cycle should be considered in physical
368 modeling to be able to make fully accurate predictions of phase separation in Fe-Cr alloys.

369
