Extreme CO Isotopic Abundances in the ULIRG IRAS 13120-5453:
An Extremely Young Starburst or Top-heavy Initial Mass Function

Abstract
We present ALMA 12CO (J = 1-0, 3-2 and 6-5), 13CO (J = 1-0), and C18O (J = 1-0) observations of the local ultraluminous infrared galaxy (ULIRG) IRAS 13120-5453. The morphologies of the three isotopic species differ, as 13CO shows a hole in emission toward the center. We measure integrated brightness temperature line ratios of 12CO/13CO ≥ 60 (exceeding 200) and 13CO/C18O ≤ 1 in the central region. Assuming optical thin emission, C18O is more abundant than 13CO in several regions. The abundances within the central 500 pc are consistent with the enrichment of the interstellar medium via a young starburst (<7 Myr), a top-heavy initial mass function, or a combination of both.

Key words: galaxies: abundances – galaxies: individual (IRAS 13120-5453) – galaxies: interactions – galaxies: starburst – radiative transfer – submillimeter: galaxies

1. Introduction
Isotopic abundances in the interstellar medium (ISM) can be used as a tracer of stellar nucleosynthesis. The 12C/13C isotope ratio is an important tracer of the relative degree of primary versus secondary processing in stars. The 12C atom is a primary species produced in intermediate- and high-mass stars (e.g., Prantzos et al. 1996). Massive stars are also responsible for the majority of 16O and 18O. The 13C atom is an intermediary species that is transformed into 14N. In the red giant phase of convective (Wilson & Matteucci 1992) and eventually released into the ISM. Massive stars are short-lived and start to enrich the ISM in 15N in ∼10^6 years, while 13C enrichment needs ∼10^9 years (e.g., Vigroux et al. 1976).

Ultra/Luminous Infrared Galaxies (ULIRGs) are extreme starbursts offering great laboratories in which to study high-mass star formation. It has long been observed that 12CO emission is unusually weak relative to 13CO (~20–40; Aalto et al. 1991; Casoli et al. 1992) compared to that from normal disk galaxies (~10; e.g., Paglione et al. 2001). Pioneering work by Casoli et al. (1992) and Henkel & Mauersberger (1993) presented several scenarios by which to explain this unusual emission ratio, such as: optical depth effects; abundance variations via some mechanism such as photo-dissociation, inflowing low-metallicity gas, or enrichment of the ISM; and a two-phase molecular medium consisting of a diffuse envelope where 12CO can better self-shield than 13CO. Recent radiative transfer modeling of the molecular gas in several ULIRGs is consistent with high [12CO]/[13CO] abundance ratios (>90; Sliwa et al. 2013, 2014; Henkel et al. 2014; Papadopoulos et al. 2014; Tunnard et al. 2015).

Recent work on the [16O]/[18O] abundance in ULIRGs using Herschel H2O and OH observations have shown varying values from ≤30 for Mrk231 (González-Alfonso et al. 2010), around 50–150 for Arp220 (González-Alfonso et al. 2014) and Zw 049.057 (Falstad et al. 2015), and ≥500 for Arp 299 (Falstad et al. 2017) and NGC 4418 (González-Alfonso et al. 2014). König et al. (2016) used Atacama Large Millimeter/submillimeter Array (ALMA) CO data to show that the [16O]/[18O] ≥ 900 for NGC 1614. The high [16O]/[18O] abundance ratios are believed to be due to inflowing gas and the low values to stellar processing.

IRAS 13120-5453 (dubbed the “Yo-yo”) is a nearby ULIRG (D_L = 144 Mpc) with a far-infrared luminosity (L_{FIR} = 1.5 \times 10^{12} L_\odot; Sanders et al. 2003) similar to that of Arp 220. The system has been classified as a post-merger (Haan et al. 2011). X-ray emission is consistent with a Compton-thick active galactic nucleus (AGN; Iwasawa et al. 2011) and contributes ~18% to the infrared luminosity (Sturm et al. 2011). The Herschel Fourier Transform Spectrometer (FTS) observed multiple high-J CO lines as well as C1, H2O, N II, OH and more (Mashian et al. 2015; Rosenberg et al. 2015; Pearson et al. 2016; Pryon et al. 2017). Pryon et al. (2017) shows that the HCN/HCO+ line ratio observed with ALMA suggests an increased HCN abundance via turbulent heating.

In this Letter, we present new ALMA Cycle 2 observations of IRAS 13120-5453 where we have detected three 12CO transitions, 13CO, and C18O J = 1–0. The morphology of the three species differs and offers insight into the mechanism that may be controlling the [12CO]/[13CO] ratio. We show that massive stars have enriched the ISM in 12C and 18O and drive the observed line ratios in IRAS 13120-5453.

2. Observations and Line Ratios
ALMA was used to observe IRAS 13120-5453 in Cycle 2 using Bands 3, 7, and 9 (Table 1). We calibrated all data sets manually in CASA v4.5.3 (McMullin et al. 2007) using standard calibration steps. We implemented two iterations of phase-only self-calibration on the 12CO data sets, which did not significantly alter the morphology of IRAS 13120-5453. We...
We then create line ratio maps to 1σ level with channels widths of 20 or 35 km s⁻¹. Integrated intensity maps were created using the CPROPs masking routine and only channels that contained masked emission were included down to 1.5σ. All maps were primary-beam corrected (Figure 1).

All three 12CO transitions have similar morphologies with a single nucleus. The 13CO J = 1–0 emission is more interesting, with no emission above 1.5σ near the central nucleus (∼0″85 × 0″3 = 590 pc × 210 pc) and two relatively strong emission regions outside of the nucleus. The region lacking emission is within the starburst region (0.5 kpc) measured by Privon et al. (2017). Interestingly, the C18O emission is relatively strong where there is no 13CO emission. In the central 0″3 x 0″3 spectrum (Figure 2), it is evident that C18O is stronger than 12CO. We note that C18O may be partially contaminated by HNCO (50.5–40.4) and several higher-energy transitions that lie on top of the C18O line. Along a line of sight, the maximum contamination is likely 30% determined from the peak of the HNCO (50.5–40.4) transition; however, we do not make any corrections since this is an upper limit to the contamination and may only contribute to part of the C18O line profile.

Selective UV photo-dissociation of the rare CO isotopologues should affect both 13CO and C18O, with the nominally rarer C18O affected the most. Thus, it could not produce the observed relative line intensity ratio variations between them, let alone boost the C18O abundance to be higher than 13CO in the inner 500 pc of IRAS 13120-5453. If optical depth effects were causing the ring, C18O should also be observed in a ring since both 13CO and C18O are assumed to be optically thin. The Band 3 observations, observed 19 days apart, have similar uv-coverage, adding confidence to the observed differences in morphology and corresponding intensities between the lines. The three 12CO maps (Figure 1) also show that as we go to a higher resolution (J = 1-0 → J = 6-5) we do not see a ring in 12CO.

Integrated brightness temperature (I = \int T_B dV) line ratio maps can offer some insight into the conditions of the molecular gas. We create the following line ratios maps:

\[
R_{12CO:13CO} = \frac{I_{12CO_{1-0}}}{I_{13CO_{1-0}}}, \quad Y_{12CO:13CO} = \frac{I_{12CO_{1-0}}}{I_{13CO_{1-0}}}, \quad Z_{12CO:13CO} = \frac{I_{12CO_{1-0}}}{I_{13CO_{1-0}}},
\]

We match the 12CO, 13CO, and C18O J = 1–0 maps to an angular resolution of 0″60 × 0″45. We then create line ratio maps by cutting emission below 2σ in each map and converting the units from Jy beam⁻¹ km s⁻¹ to K(T_B) km s⁻¹ (Figure 3). The R_{12CO:13CO} ratio shows a wide range of values from ∼10 to over 250. While values of around 30 are common for local ULIRGs (e.g., Sliwa et al. 2012, 2013, 2014, 2017; Sliwa & Downes 2017), values exceeding 100 have never been observed before in local ULIRGs. The Y_{12CO:13CO} ratio ranges from 0.2 to over 4. Values below 1 are rare in extragalactic systems where normal disk galaxies have an average Y_{12CO:13CO} value of ∼6 and normal starbursts show Y_{12CO:13CO} values of ∼3 (Jiménez-Donaire et al. 2017). Arp 220 (Greve et al. 2009; Matsushita et al. 2009) and the high-z ULIRG SMM J2135-0102 (Danielson et al. 2013) show a Y_{12CO:13CO} ratio of 1, while the LIRG remnant, NGC 2623, shows a Y_{12CO:13CO} ratio of ∼1.8 (K. Sliwa et al., in preparation). The Z_{12CO:13CO} ratio ranges from ∼20–140 and are similar to those of Mrk 231 (González-Alfonso et al. 2010), Arp 220 (González-Alfonso et al. 2014), and Zw 049.057 (Falstad et al. 2015).

### 3. Extreme Isotopic Abundances

We argue that IRAS 13120-5453 has an extreme isotopic abundance ratio when compared to normal star-forming galaxies. The brightness temperature line ratio of species A and B can be expressed as

\[
R = \frac{I_A}{I_B} = \frac{T_{A}^{\text{ex}} (1 - e^{-\gamma A})}{T_{B}^{\text{ex}} (1 - e^{-\gamma B})},
\]

where T_{ex} is the excitation temperature and \(\gamma\) is the optical depth of the particular species and transition. For simplicity, we assume local thermal equilibrium (LTE; i.e., \(T_A^{\text{ex}} = T_B^{\text{ex}} = T_{\text{kin}}\)). (Significant radiative trapping for the abundant species can give T_{ex} < T_{\text{kin}}.) If species B is optically thin and

Notes.
- Other lines present in the data will be discussed in a forthcoming paper (K. Sliwa et al., in preparation).
- Uncertainties in curved and square brackets denote measurement and calibration uncertainties, respectively.
Figure 1. Integrated intensity maps for IRAS 13120-5453: (a) $^{12}$CO $J=1$–0, (b) $^{12}$CO $J=3$–2, (c) $^{12}$CO $J=6$–5, (d) $^{13}$CO $J=1$–0, and (e) C$^{18}$O $J=1$–0. The ellipse in the bottom-left corner represents the synthesized beam.
species A is optically thick, then

$$R \sim \frac{1}{\tau_A} \sim \frac{[A]}{[B]} \tau_A.$$  \hspace{1cm} (2)

If \(^{12}\text{CO}\) is optically thick, the line ratios \(R_{10}\) and \(Z_{10}\) are lower limits to the relative abundance of \(^{12}\text{CO}\) to \(^{13}\text{CO}\) and \(^{18}\text{O}\), since the observed line ratio is attenuated by the optical depth of \(^{12}\text{CO}\). Since \(R_{10}\) and \(Z_{10} \gg 1\), both \(^{13}\text{CO}\) and \(^{18}\text{O}\) must be optically thin. Thus, the \(R_{10}\) line ratio of \(<1\) implies that \(^{18}\text{O}\) is more abundant than \(^{13}\text{CO}\) in the central region; this would still be true even if the HNCO contamination were to reach 50%.

4. Root of the Extreme Abundances

**Photo-dissociation:** Since \(^{18}\text{O}\) is bright relative to \(^{13}\text{CO}\), we can rule out selective photo-dissociation as the dominant mechanism, since both \(^{18}\text{O}\) and \(^{13}\text{CO}\) would be destroyed by UV radiation.

**Fractionation:** The most important carbon isotope exchange is

$$^{13}\text{C}^+ + ^{12}\text{CO} \rightarrow ^{13}\text{CO} + ^{12}\text{C}^+ + \Delta E.$$ \hspace{1cm} (3)

(Watson et al. 1976), where the forward reaction dominates in cold environments (<30 K) favoring the formation of \(^{13}\text{CO}\). In hot environments, both directions have equal probability (Roueff et al. 2015). We use the non-LTE code RADEX (van der Tak et al. 2007) and a Bayesian likelihood code (Kamenetzky et al. 2012) to constrain the molecular gas physical conditions within the ∼400 pc central region using only the \(^{12}\text{CO}\) observations. We fit the \(^{12}\text{CO} J=1-0\) line with a Gaussian profile of FWHM = 375 km s\(^{-1}\). The most probable solution is warm, dense molecular gas with a \(T_{\text{kin}} = 130^{+400}_{-77}\) K, log \((n_{\text{H}_2}) = 4.2^{+2.4}_{-0.0}\) cm\(^{-3}\), and log\((M(H_2)/M_\odot) = 7.8^{+1.0}_{-0.1}\). Since the molecular gas is not cold enough for the forward reaction to dominate, we can rule out fractionation as a possible mechanism affecting the abundance. We also note that \(^{18}\text{O}\) does not undergo fractionation and should reflect stellar processing (Langer et al. 1984).

**Infalling Gas:** The merger process can drive a gas inflow toward the nuclear regions (e.g., Hopkins et al. 2006; Kewley et al. 2006; Ellison et al. 2008). The Galaxy has an increasing radial gradient in the \([^{12}\text{CO}]/[^{13}\text{CO}]\) abundance ratio, ranging from 30 in the center to >100 at large radii (e.g., Milam et al. 2005). Jiménez-Donaire et al. (2017) have shown that a trend with \([^{13}\text{CO}]/[^{18}\text{O}]\) exists in disk galaxies as well with an average value of 6.0 ± 0.9. Analyses of close galaxy pairs have shown that their metallicities are lower than similar field galaxies (Kewley et al. 2006; Ellison et al. 2008). Rupke et al. (2008) found that the dilution of the nuclear metallicity (Z) due to gas inflow is \(Z_{\text{final}}/Z_{\text{initial}} \sim 0.5\); therefore, if we assume an initial \([^{12}\text{CO}]/[^{13}\text{CO}]\) ratio of 30, we would expect a final ratio of ∼60. This would not be sufficient to explain the observed line ratios in the central regions, particularly the brighter \(^{18}\text{O}\) emission.

**Nucleosynthesis:** Enrichment of the ISM via massive stars is a likely mechanism. Massive stars are the dominant sources of \(^{12}\text{C}, ^{16}\text{O},\) and \(^{18}\text{O}\), while \(^{13}\text{C}\) is predominately released from low/intermediate-mass stars. Simulations show that the metallicity in the merger increases when the star formation rate increases significantly, especially near the end of the merger process (Torrey et al. 2012).

For nucleosynthesis enrichment to be plausible, the starburst must be young. With a normal initial mass function (IMF) such as the Kroupa IMF (e.g., Kroupa 2001) within ∼6 Myr, all stars >30\(M_\odot\) will have gone supernova, ejecting material. Using the nucleosynthesis yield calculations for core-collapse supernovae
(CCSNe) of Nomoto et al. (2006) and assuming a total star-forming molecular mass of $10^9 M_\odot$ and an initial metallicity of $Z = 0.02$ ($\sim Z_\odot$), the $^{13}$CO/$^{12}$CO value of the ejected material after 6 Myr will be $\sim 575$, while after 7 Myr, when all stars above $25 M_\odot$ will have gone supernova, the $^{13}$CO/$^{12}$CO will be $\sim 60$.

If the starburst is older ($>7$ Myr), an alternative solution is a top-heavy IMF. Bartko et al. (2010) find a top-heavy IMF for the Galactic center of $dN/dm \propto m^{-0.45 \pm 0.3}$. Habergham et al. (2010) also invoke a top-heavy IMF to explain the excess of CCSNe in interacting/mergers galaxies when compared to isolated galaxies. Assuming that only stars of $10^{–130} M_\odot$ will eject material via CCSNe, a Kroupa IMF will produce a $^{13}$CO/$^{12}$CO abundance of 40 while a flat, top-heavy IMF ($\phi_m \propto m^0$) will produce a $^{13}$CO/$^{12}$CO abundance of 270. While a flat IMF is an arbitrary choice, if the starburst is older than $\sim 6$ Myr a top-heavy IMF of some variety is required to explain our observed abundances in the central region. We also note that a combination of both a young-starburst and a top-heavy IMF is also plausible. Future work into the star formation history of IRAS 13120-5453 is required to clarify the starburst-age/IMF degeneracy.

We thank the referee for suggestions and comments that greatly improved this manuscript. K.S. thanks E. Schinnerer for useful discussions. This paper uses the following ALMA data: ADS/JAO.ALMA#2012.1.00306.S +ADS/JAO.ALMA#2013.1.00379.S. ALMA is a partnership of ESO (representing its member states), NSF (USA) and NINS (Japan), together with NRC (Canada) and NSC and ASIAA (Taiwan), and KASI (Republic of Korea), in cooperation with the Republic of Chile. The JAO is operated by ESO, AUI/NRAO, and NAOJ. The NRAO is a facility of the NSF operated under cooperative agreement by Associated Universities, Inc.
