The circumstellar envelope around the S-type AGB star W Aql
Effects of an eccentric binary orbit

ABSTRACT

Context. Recent observations at subarcsecond resolution, now possible also at submillimeter wavelengths, have shown intricate circumstellar structures around asymptotic giant branch (AGB) stars, mostly attributed to binary interaction. The results presented here are part of a larger project aimed at investigating the effects of a binary companion on the morphology of circumstellar envelopes (CSEs) of AGB stars.

Aims. AGB stars are characterized by intense stellar winds that build CSEs around the stars. Here, the CO(J = 3 → 2) emission from the CSE of the binary S-type AGB star W Aql has been observed at subarcsecond resolution using ALMA. The aim of this paper is to investigate the wind properties of the AGB star and to analyse how the known companion has shaped the CSE.

Methods. The average mass-loss rate during the creation of the detected CSE is estimated through modelling, using the ALMA brightness distribution and previously published single-dish measurements as observational constraints. The ALMA observations are presented and compared to the results from a 3D smoothed particle hydrodynamics (SPH) binary interaction model with the same properties as the W Aql system and with two different orbital eccentricities. Three-dimensional radiative transfer modelling is performed and the response of the interferometer is modelled and discussed.

Results. The estimated average mass-loss rate of W Aql is Ṁ = 3.0 × 10^{-6} M⊙ yr^{-1} and agrees with previous results based on single-dish CO line emission observations. The size of the emitting region is consistent with photodissociation models. The inner 10'' of the CSE is asymmetric with arc-like structures at separations of 2−3'' scattered across the denser sections. Further out, weaker spiral structures at greater separations are found, but this is at the limit of the sensitivity and field of view of the ALMA observations.

Conclusions. The CO(J = 3 → 2) emission is dominated by a smooth component overlayed with two weak arc patterns with different separations. The larger pattern is predicted by the binary interaction model with separations of ∼10'' and therefore likely due to the known companion. It is consistent with a binary orbit with low eccentricity. The smaller separation pattern is asymmetric and coincides with the dust distribution, but the separation timescale (200 yr) is not consistent with any known process of the system. The separation of the known companions of the system is large enough to not have a very strong effect on the circumstellar morphology. The density contrast across the envelope of a binary with an even larger separation will not be easily detectable, even with ALMA, unless the orbit is strongly asymmetric or the AGB star has a much larger mass-loss rate.

Key words. stars: AGB and post-AGB – circumstellar matter – binaries: general – submillimeter: stars
that PNe formation is more common among binary stars (e.g. Moe & De Marco 2006).

It is likely – and recent, high spatial resolution observations have also shown (e.g. Maercker et al. 2012; Mauron et al. 2013; Cernicharo et al. 2015; Kim et al. 2017) – that the shaping of the circumstellar material will start on the (late) AGB. Circumstellar wind dynamics in binary systems with a mass-losing primary are therefore a very active field of research (e.g. Kim et al. 2015; Toupin et al. 2015). To provide observational constraints for recently developed 3D hydrodynamical models (e.g. Mohamed & Podsadiłowski 2012), we have designed a project for ALMA to observe the CO gas distribution and kinematics around known binary AGB stars. Resolved images of the binary pair are available for the initial sample stars, R Aqr, o Cet (Mira), W Aql, and π′ Gru, and the sources cover extensive ranges in the important modelling parameters, i.e. binary separation, \( a \approx 20–400 \) AU, and AGB wind expansion velocity, \( v_w \approx 10–100 \) km s\(^{-1}\). Initial results have been published in Ramstedt et al. (2014, on Mira), Ramstedt et al. (2015, also on W Aql, and π′ Gru); and Doan et al. (2017, on π′ Gru).

This paper focuses on the S-type AGB star W Aql. S-type stars are classified by the presence of ZrO bands and are thought to represent an intermediate evolutionary stage where the atmospheric C/O-ratio is close to 1. W Aql has a known companion at a separation of \( a = 0.46'' \) (Ramstedt et al. 2011) or \( \approx 180 \) AU, and the distance to the system is estimated to 395 pc (Danilovich et al. 2014). Several resolved observations of the system and the circumstellar material exist. The dust emission at 11.15 \( \mu \)m from the inner arcsecond around W Aql was measured using the three-element Infrared Spatial Interferometer (ISI) in 2004 (Tatebe et al. 2006). The observations showed brighter emission on the east side of the source indicating dust excess very close to the star (0′′.5 – 200 AU at \( D = 395 \) pc). Assuming a typical outflow velocity of 20 km s\(^{-1}\), Tatebe et al. (2006) suggest that a dust shell has been expelled from the star “within the last 35 years” (from 2004). The dust distribution on a 1′ scale around W Aql was imaged by Ramstedt et al. (2011) using polarimetry to detect the dust scattered light. This revealed an asymmetric dust distribution around the star with more dust on the south-west side. The first resolved Hubble Space Telescope (HST\(^1\)) image of the binary pair was also presented. The companion was later classified by Danilovich et al. (2015) as a F8 to G0 main-sequence star. Danilovich et al. (2015) established that the known companion has an effective temperature in the range 5900–6170 K and a mass of 1.04–1.09 \( M_\odot \). They find a mass for the AGB star of 1.04–3 \( M_\odot \). The thermal dust emission from W Aql (on even larger scales) was imaged by Herschel/PACS as part of the Mass-loss of Evolved StarS (MESS) key program (Groenewegen et al. 2011). Mayer et al. (2013) investigated the large-scale dust distribution, and found that the south-west dust asymmetry also extends to larger scales.

Danilovich et al. (2014) modelled the molecular line emission from W Aql assuming a spherically symmetric circumstellar envelope (CSE), and derived the abundances of several chemically important molecules (including the first detection of NH\(_2\)C in an S-type star) and a mass-loss rate of \( M = 4.0 \times 10^{-8} \) \( M_\odot \) yr\(^{-1}\). In this paper the 1D CO radiative transfer model is further constrained by the ALMA data. The data is presented in Sect. 2, and the 1D radiative transfer modelling to estimate the average mass-loss rate in Sect. 3.1. The 3D models used to analyse the wind shaping effects due to the companion are introduced in Sects. 3.2 and 3.3. In Sect. 4 the results from the observations and the models are given, and further discussed in Sect. 5. Finally, conclusions are drawn in Sect. 6.

### 2. Observations

W Aql was observed with ten Atacama Compact Array (ACA) 7 m antennas on 6 March 2014. It was also observed on 20 March 2014 with 33, and on 14 April 2014 with 34 main array 12 m antennas. The main array observations were performed as a ten-pointing mosaic covering an area of approximately 30′′ × 30′′. The same area was covered by the ACA in three mosaic pointings. Finally, it was observed with three 12 m antennas of the Total Power (TP) array on the 12 June 2015. The correlator was set up with four spectral windows ~2 GHz in width centred on 331, 333, 343, and 345 GHz to cover the \(^{12}\)CO and \(^{13}\)CO \( J = 3 \rightarrow 2 \) lines in the same setting. The total observing time was 23 min for the ACA, and 7.25 min and 7.3 min for the 12 m array on the first and second run, respectively, and 67 min total time for the TP array. Baseline lengths range from 15 to 558 m for the main array, and from 9 to 49 m for the ACA. This results in a maximum recoverable scale of ~7′′ for the main array and ~12′′ for the ACA. The restoring beam of the TP observation is 18′′.84 × 18′′.84 at 345.2 GHz. Calibration was carried out following standard procedure. The quasar J1911-2006 was used as complex gain calibrator; quasar J1924-2914 was used as bandpass calibrator; and Ceres, Titan, and quasar J1924-292 were used as flux calibrators. Total power observations are calibrated using standard single-dish observing procedures with regular pointing checks and focus calibration. The intensity scale is converted from Kelvin to Janskys using conversion factors of 46.723, 48.568, 47.036, and 48.196 across the four different spectral windows. The main array data was combined with the ACA data, which was weighted by a factor of 0.25 to account for the lower sensitivity of the 7 m antennas, and the combined data was imaged. The combined main array+ACA visibilities were finally combined with the TP visibility data using the CASA task SD2VIS\(^2\). A continuum image was made using the emission free channels from all spectral windows, but the continuum was too weak to be used for self-calibration of the offset mosaic pointings. The position and measured continuum flux density at 338 GHz is determined from image fitting and given in Table 1. Final imaging was done after subtracting the continuum and averaging to reach a spectral resolution of 2 km s\(^{-1}\). The beam of the final images has a full width at half maximum of 0′′.47 × 0′′.41, and a position angle of 65.3′′. The rms noise level in the emission-free channels reaches 15 mJy/beam. Previous \(^{12}\)CO \( J = 3 \rightarrow 2 \) line emission observations with APEX (Ramstedt et al. 2009) measured a peak intensity of ~145 Jy showing that the same amount of flux was recovered by the combined ALMA observations (Fig. 1, left). The \(^{12}\)CO \( J = 3 \rightarrow 2 \) line emission is centred at a local standard of rest (LSR) velocity of \( v_{\text{LSR}} = -25.5 \) km s\(^{-1}\).

3. Analysis

3.1. Determining the average mass-loss rate

Danilovich et al. (2014) modelled all the available single-dish CO rotational lines of W Aql (up to $J = 25 \rightarrow 24$ in the vibrational ground state, $v = 0$) using the non-LTE, non-local Monte Carlo radiative transfer code described in Schöier & Olofsson (2001), and assuming a distance of 395 pc. The radiative transfer code assumes a spherically symmetric CSE created by a constant mass-loss rate. For a further description on the assumptions made for the W Aql model in particular and the code in general see Danilovich et al. (2014) and Schöier & Olofsson (2001), respectively.

The model by Danilovich et al. (2014) is further constrained here by the brightness distribution derived from the CO($J = 3 \rightarrow 2$) map from ALMA. The CO envelope size was previously based on the photodissociation models by Mamon et al. (1988), Stanek et al. (1995). Now the brightness distribution provides direct constraints on the size of the CO envelope, which can be treated as a free parameter. The CO($J = 3 \rightarrow 2$) brightness distribution is derived by smoothing the full image cube to a resolution of 0′′6 using imsmooth in CASA. Then the brightness distribution is measured by the integrated line flux (within a 0′′6 beam) at increasing distances from the centre (determined by the position of W Aql A) in four directions (north, east, south, and west) and finally averaged over direction. The corresponding brightness distribution (using the same beam size and radii) is calculated from the radiative transfer modelling results and compared to the observed values until a fit is found (Fig. 2). The error in the measured line flux is assumed to be 10% with the variation across the different directions taken into account.

3.2. Hydrodynamical modelling

W Aql was modelled using the Evolved Stellar Interactions with GADGET in 3D (ESI-Gadget code), which is based on a modified version of the collisionless and gasdynamical cosmological code GADGET2 (Springel 2005). The fluid equations are solved using smoothed particle hydrodynamics (SPH), a Lagrangian method particularly suited to studying flows with arbitrary geometries. Modules include radiative cooling, stellar winds, and binary interactions (Mohamed & Podsiadlowski 2007; Mohamed et al. 2012).

The parameters assumed for the models are given in Table 2; the stars are treated as point masses, and two different eccentricities for the binary orbit were assumed – $e = 0.2$ and $e = 0.6$. The
stellar wind from the AGB star was simulated by periodically injecting particles at a boundary given by the surface of the star. An acceleration parameter was added to the momentum equation to ensure that a smooth continuous wind with a terminal velocity of 16.5 km s\(^{-1}\) was produced. It was not possible to resolve the surface of the companion; this was instead treated as an accretion boundary (the boundary radius is set to 1 AU) where particles lose mass as they approach the companion and are removed from the simulation once they are 1% of their original mass. The wind particles are injected into initial vacuum conditions, thus the outermost arc is denser than it would be otherwise. Each simulation was run for long enough to ensure that this region is outside the observed ALMA field of view. After \(1.1 \times 10^4\) yr of evolution, \(6 \times 10^5\) particles had been injected. The initial mass of the particles is determined empirically so that it leads to the estimated mass-loss rate. They all have the same initial mass and the mass of the AGB star does not change as these particles are injected. Over the timescales considered, the amount of mass injected is insignificant (relative to the stellar mass). The output from these high-resolution models was then gridded using the SPH cubic spline kernel to a 512\(^3\) grid in order to be used as input for the post-processing radiative transfer routine.

### 3.3. Post-processing radiative transfer

The output from the hydrodynamical model, i.e. 512\(^3\) grids of the H\(_2\) number density, the temperature, and the velocity distributions, is used as input to calculate the expected CO line emission. The non-LTE, non-local 3D radiative transfer code LIME (Line Modelling Engine, Brinch & Hogerheijde 2010) is used to calculate the CO level populations and solve the radiative transfer equations. Grid points are distributed across the computational volume using Delauney triangulation and the probability for placing a grid point is weighted with the density. Each grid cell is the corresponding Voronoi cell where the local conditions (density, temperature, excitation, etc.) are constant across each cell. For the calculations presented here, 100,000 grid points were used in a volume with a radius of 15,000 AU. A constant CO/H\(_2\) fractional abundance of \(6.0 \times 10^{-4}\) is assumed for the S-type star. The molecular excitation is calculated including 41 rotational transitions in the vibrational ground state and first excited state. Higher energy levels are not expected to be significantly populated. Collisions with H\(_2\) are included assuming an ortho-to-para ratio of 3. Collisional rate coefficients, as well as energy levels and radiative transition probabilities, are taken from Schöier et al. (2005). For the continuum thermal dust emission, amorphous silicate grains are assumed (Justtanont & Tielens 1992).

The output images from the radiative transfer model are produced over 100 channels using a spectral resolution of 1 km s\(^{-1}\), and a spatial resolution of 0\('\)r. The source distance is assumed to be 395 pc. Finally, the uv-coverage of the combined ALMA arrays is taken into account by running this image through the ALMA simulator using the array configurations at the time of the W Aql observations (in Cycle 1).

### 4. Results

#### 4.1. Wind properties

The average mass-loss rate during the creation of the CSE probed by the observations is estimated to be \(M = 3.0 \times 10^{-6} M_\odot\) yr\(^{-1}\). The line widths are best fitted by a slowly accelerating velocity field which reaches the terminal expansion velocity of \(v_e = 16.5\) km s\(^{-1}\) at \(r \approx 2 \times 10^{16}\) cm, i.e. about 100 times the inner radius of the (modelled) CSE. This agrees well with previous estimates of the average mass-loss rate during the creation of the CSE around W Aql. Also, the size of the CSE required to produce the CO(3–2) brightness distribution (Fig. 2) agrees with the results from the model by Mamon et al. (1988).

#### 4.2. Circumstellar morphology

The channel maps of the CO\((J = 3 \rightarrow 2)\) emission around W Aql (see Appendix A) shows a circumstellar CO emission distribution quite similar to that seen around R ScI and other stars (e.g. Maercker et al. 2016). The emitting region starts out small and essentially circular at the blue edge of the line, reaches maximum size at the line centre where several prominent arc-like structures are seen, and then shrinks again toward the red line edge. The small-scale structure seen closer to the line centre is more well-defined, while the emission appears rather smooth closer to the line edges. Unlike R ScI, W Aql is not surrounded by a spherically symmetric thin gas shell. Figure 1 (middle, right) shows the image averaged over the central channels of the line (Fig. 1, left). The strength of the brightness distributions in the four different directions over which it was measured vary only marginally (Sect. 3.1), indicating that most of the line emission comes from a smooth extended component. In Fig. 1 (middle, right), however, the emission appears slightly brighter and less smooth on the west side and in particular on the south-west side of the source. There are prominent arc-like structures close to the star (within ±3\(^\circ\)), while these structures become less well-defined further out. In Fig. 1, right, the arc-like structures are marked since the contrast between the arcs and the background is weak. The full imaged area reaches about 20\('\) from the position of the continuum source, but structures beyond ~12\('\) are less reliable, due to the rapidly declining image quality when moving away from the image centre.

Figure 3 shows position-velocity (PV) diagrams generated over a narrow slit (9 pixels) across the north-south and east-west directions at a position angle (PA) of 0\(^\circ\) and 90\(^\circ\). The right diagram is generated along the apparent binary axis as it appears in the resolved HST image (at PA = 35\(^\circ\), Ramstedt et al. 2011). In the PV diagrams, the asymmetry is even more pronounced, and the arc-like structures on the west and south-west sides (marked in Fig. 1) appear more clearly. The contrast is weak, but there is a hint at an arc periodicity of about 3–4\('\) on both the east and west sides in the middle PV diagram at PA = 90\(^\circ\). In the central-channel image in Fig. 1, middle and right, the arc-like structures appear clearest along the north-east-south-west diagonal, or along the binary axis, which is also shown in the PV-diagram at PA = 35\(^\circ\) (Fig. 3, far right) where the arcs are separated by 2–3\('\). However, it should be noted that the orientation of the orbit is not known and the direction of the binary axis in the HST image is only as it appears projected onto the plane of the sky.

#### 4.3. Binary interaction model results

Figure 4 shows the results from the LIME radiative transfer model. The far left image is the output image modelled at 0\('\)2 resolution before being convolved with the response of the interferometer, and generated over the central channels.
Fig. 3. Left: position-velocity diagram across the north-south direction (PA = 0°). The contours are drawn at 3, 5, 10, 20, and 40σ (where σ is measured over the emission-free channels). Middle: position-velocity diagram across the east-west direction (PA = 90°) showing the brighter and more structured emission on the west side of the stars. Right: position-velocity diagram along the binary axis (PA = 35°) showing the structure within the south-west bright emission (Fig. 1).

Fig. 4. Results from the radiative transfer modelling of the two hydrodynamical models with different orbital eccentricities. The upper row shows the results from the e = 0.2 model. The lower row shows the results from the e = 0.6 model. The far left image shows the output of the full model over the central channels (analogous to Fig. 1) without taking the response of the interferometer into account. The middle left image shows the output from the ALMA simulator. The two right images show PV-diagrams generated perpendicular to the model binary axis (PA = 0°) and along it (PA = 90°), respectively. The contours are drawn at 35, 50, 75%-fractions of the peak emission.

(analogous to Fig. 1). As seen in previous publications (Mastrodemos & Morris 1998; Mohamed & Podsadlowski 2012; Kim et al. 2015), the binary companion will shape a spiral pattern in the outflowing CSE of the AGB star. For a system with the same properties as W Aql (orbital period = 1394/5 yr, \(v_{\text{exp}} = 16.5 \text{ km s}^{-1}\)), the arc separation will be 10–12′. The emission contrast between the arcs and the interarc regions is a factor of \(\leq 2\) for the \(e = 0.2\) model and \(\leq 3\) for the \(e = 0.6\) model. The model binary axis is along the east-west direction.

The middle left image in Fig. 4 shows the emission as it would be seen by ALMA using the same main array, ACA, and TP configurations as used for the W Aql observations in Cycle 1 (we note that the image size is different to that in the far left image). The full channel maps are shown in Figs. A.2 and A.3. This shows particularly well the difficulty in recovering weakly contrasting features even with ALMA, and also how insufficient cleaning can introduce false features, which emphasizes that weak emission structures should not be overinterpreted. This image was generated using the CASA task simanalyze without the careful, iterative, multiscale cleaning used when imaging the real data, and therefore the fidelity is worse than in the W Aql images in Figs. 1, 3, and A.1.

The two right images show PV diagrams generated from the middle left image taking the interferometer response into account. The middle right diagram shows the emission distribution along an axis perpendicular to the model binary axis (PA = 0°); the far right diagram shows the emission along the binary axis (PA = 90°). The diagrams show the brightest (“real”) arcs in the image together with some weak (false) features. When the observational set-up from Cycle 1 is used, the PV diagrams show that only one or two arc-like structures (\(\sim 10''\)) with larger separations can be detected, and that a larger area would have to be
mapped in order to draw firm conclusions about the eccentricity of the orbit of the two resolved companions in the W Aql system. The upper row of Fig. 4 shows the results from the $e = 0.2 \text{ model}$, and the lower row shows the results from the $e = 0.6 \text{ model}$. A difference compared to a circular orbit (see e.g. Maercker et al. 2012) introduced when varying the eccentricity is that the distribution of circumstellar material across the rotation axis will be asymmetric and there will be more material on the periastron side. The contrast across the rotation axis will grow with eccentricity, as will the contrast between the arcs and the interarc regions (see above and Fig. 4). Also, as seen in Fig. 4, the arc separation on the apastron side is larger when the eccentricity is larger.

5. Discussion

5.1. Comparison to previous resolved observations of the CSE around W Aql

The dust shell detected by Tatebe et al. (2006) would not be resolved by the ALMA observations, but it is possible that it is an inner extension of the arcs seen close to the star (see Fig. 1).

The dust-scattered emission over about 1′ around W Aql imaged by Ramstedt et al. (2011), using the PolCor instrument, showed that the circumstellar dust is distributed asymmetrically around the star with more dust on the south-west side. Figure 5 shows the CO emission contours from Fig. 1 overlayed on the PolCor image. The figure shows that the dust and CO gas distributions overlap on these scales, and that the south-west emission (density) enhancement appears in both images. The small-scale structures, or arcs, seen in the central-channel CO line image (Fig. 1) are not seen in the scattered-light R-band image since the arcs, which appear at different velocity channels (Appendix A), are smeared in the dust emission image.

The large-scale morphology of the circumstellar dust around W Aql has been studied in detail by Mayer et al. (2013) using images from Herschel/PACS. The dust distribution appears elliptical with brighter emission reaching further from the star along the east-west axis (to 40−45′′ ~ 16 000 AU at $D = 395 \text{ pc}$). More diffuse emission extends further on the west side, but is not apparent on the east side where the emission appears truncated by a large arc-like feature, possibly a bow-shock (although not aligned with the space motion as calculated by Mayer et al. 2013).

The inner region of the PACS images (overlapping with the region mapped by ALMA) shows a slight elongation to the south-west, but there is also bright emission on the east side which does not have an apparent counterpart in the gas emission images. By assuming an orbital period $\lesssim 1000 \text{ yr}$ and a wind velocity of $20 \text{ km s}^{-1}$, Mayer et al. (2013) estimate an expected arc separation of $12\arcsec/5$ and try to fit the PACS data with different Archimedian spirals with some success. Figure 3 (right) shows the PV diagram of the ALMA data along PA = 0°, i.e. the north-south direction, and although the emission contrast is very weak and the image fidelity decreases beyond $\sim 12\arcsec$, recurring arcs of a similar periodicity to that suggested by Mayer et al. (2013) are seen.

5.2. Comparison to the binary interaction models

The hydrodynamical models using the known parameters of the W Aql system as input, and assuming a constant mass-loss rate and expansion velocity, produce a large spiral pattern with $\sim 10^{\prime\prime}$ spiral-arm separation. The main difference between the two models with different eccentricities is the contrast between the arcs of the spiral on the apastron versus periastron side. From the $e = 0.2\text{-model}$ there is almost no contrast between the two sides, while the $e = 0.6 \text{ model}$ essentially lacks arcs on the apastron side (Fig. 4). The inner $10^\prime$ of the W Aql CSE show a clear contrast between the west and east sides, with smoother declining emission on the east side and arc-like structures at separations of $2−3^\prime$ perpendicular to the apparent binary axis (Figs. 1, middle and right, and 3, left and right). This close arc pattern is not seen in the models because no process that could produce density variations on a timescale of $\sim 200 \text{ yr}$ was included.

There is a hint of arc-like structures at larger separations in the observations (best seen in the PA = 90° PV diagram, Fig. 3, middle), but the contrast between the smooth component and the arcs is very weak (about a factor of 2, in agreement with the $e = 0.2 \text{ model}$) and they appear in the outer regions where the image is less reliable. There is no apparent asymmetry between the brightness of arcs with larger separations when comparing the north and south sides, but it is difficult to evaluate using the current data. As already mentioned above, a deeper and larger image would be necessary in order to draw firm conclusions about the orbit eccentricity of the known companion in the W Aql system.

5.3. Circumstellar gas envelope of W Aql

To summarize, the CO(3−2) line emission from the W Aql system is entirely dominated by a smooth symmetric component (Fig. 2) from the gas envelope generated by an average mass-loss rate estimated to $\dot{M} = 3.0 \times 10^{-6} \text{ M}_\odot \text{ yr}^{-1}$, i.e. rather high for an S-type star (Ramstedt et al. 2009). Superimposed on the smooth component, there appears to be a double arc pattern in the CSE of W Aql. It is likely that the arcs at greater separations ($10^\prime$) are caused by the gravitational pull on the circumstellar gas by the known companion at 0′/46. There is no apparent asymmetry between the arc-like structures at greater separations on different sides of the system, as seen in the $e = 0.6 \text{ model}$, and the contrast between the arcs and interarc region agrees with the output from the $e = 0.2 \text{ model}$, but this is also difficult to evaluate with the current data set. The closer arcs, marked in Fig. 1 (right), could be formed via a number of different processes: a second closer companion (or a massive planet) with an eccentric orbit, a recent change in the wind velocity (which would have to decrease by a factor of 3−4), mass-loss-rate variations, etc. Density
variations over the same timescale are also seen in the carbon star IRC+10216 (e.g. Leão et al. 2006). In that star, the optically thick CSE could block heat from escaping the dust formation region and thereby stop grain formation temporarily, causing episodic mass loss on the same timescales (Eriksson et al. 2014); however, in the S-type CSE of W Aql, this is a less likely explanation. The pulsation/conviction timescale is much shorter than the arc-formation timescale, and therefore is probably not the cause of the arcs at smaller separations. The inner arc structure is clearly asymmetric, and co-incident with the previously imaged dust emission enhancement. It is possible that the disappearing SiO masers of W Aql (Ramstedt et al. 2012) hint that a disruption of the inner CSE (<5 R\textsubscript{\ast}) is occurring, which could lend weight to the presence of an additional, closer companion. If this is the case, then the third body approached sufficiently close to the star to disrupt the SiO maser zone during 2010–2011, but this is highly speculative. Closer imaging and monitoring of the system to look for dust formation variations (Ohnaka et al. 2016) or a third system body would be very interesting and would help to understand the shaping of the W Aql CSE.

6. Conclusions

The observations of W Aql are part of a project with the aim of achieving a better understanding of how a binary companion will shape the expanding CSE around a mass-losing AGB star by observing stars with a known binary companion. The idea is that this would provide better constraints for the models of the interaction, as opposed to the more common strategy of inferring the companion from the shape of the CSE alone. However, even when the separation is known, this has proven perhaps more complicated than initially hoped (Ramstedt et al. 2014; Doan et al. 2017), and additional information about the systems, orbits, more exact distances, properties of the companion, etc., are required to fully understand the systems and to explain the shaping processes.

In the W Aql system, the circumstellar gas distribution is moderately affected by the interaction with the companion, which is also to be expected given the relatively large separation between the two stars (close to 200 AU at 395 pc). Instead, the inner region of the CSE around the W Aql system is asymmetric and shows an arc pattern with a separation of 2′′–3′′, predominately on the south-west side of the sources and overlapping with the previously mapped dust emission. The physical processes behind the south-west asymmetry and the arcs at smaller separations are not known, and cannot be easily linked to any known properties of the system.

Acknowledgements. The authors would like to thank the staff of the Nordic ALMA ARC node for their support, availability, and continuous efforts in helping produce maximum quality data products. This paper makes use of the following ALMA data: ADS/JAO.ALMA#2012.1.00524.S. ALMA is a partnership of ESO (representing its member states), NSF (USA), and NINS (Japan), together with NRC (Canada) and NSC and ASIAA (Taiwan), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/NRAO, and NAOJ. S.M. is grateful to the South African National Research Foundation (NRF) for a research grant. Appendix A: Channel maps

Fig. A.1. ALMA CO(3–2) channel maps. The LSR velocity of each channel is given in the upper right corner legend. Contours are given at 10, 20, 30, and 40$\sigma$, where $\sigma$ has been measured in the emission-free channels. The blue cross marks the peak of the continuum emission.
Fig. A.2. Channel maps from the model with $e = 0.2$ (see text for explanation). The velocity relative to the line centre of each channel is given in the upper right corner legend. Only the blue-shifted emission is shown since the maps are completely symmetric around the line centre.
Fig. A.3. Channel maps from the model with $e = 0.6$ (see text for explanation). The velocity relative to the line centre of each channel is given in the upper right corner legend. Only the red-shifted emission is shown since the maps are completely symmetric around the line centre.
