One of the many challenges of chemical biology is the design and the understanding of the mechanisms of small DNA-binding molecules. Since most of the DNA-associated processes occurring in the cell could be inhibited by a molecule with a high DNA-binding affinity, controlling the action using external stimuli would be of tremendous utility for e.g. chemotherapeutics. Ultimately, a molecule for this purpose should show no or very small affinity for the DNA double helix in the "passive" form. Upon activation the molecule should interconvert to a form that binds strongly to DNA to inhibit the targeted process. Here, we report a photochromic molecule from the spiropyran \(^3\) (SP) family that can be activated using UV light from a form that shows no signs of interaction with DNA to a form that binds to DNA by intercalation. The corresponding deactivation can be achieved by visible light, i.e., the DNA-binding process is fully reversible using light as the only stimulus.

The idea of switching the state of photochromes in order to control various DNA-associated processes has been demonstrated before. However, in the vast majority of these pioneering studies, the approach has been to covalently link photochromic units to short single-stranded oligonucleotides\(^6\)-\(^12\), while other authors have been targeting mismatch-containing \(11\)-mers\(^3\). Our approach surmounts the need of covalently modifying the targeted DNA molecules and the principle is applicable on naturally occurring DNA, making it much more suitable for any practical biological application.

Chart 1 shows the structures and the isomerization scheme of photochromic spiropyran \(1\) used in this work. The thermally stable spiropyran form \(1\) is isomerized to the ring-opened merocyanine form \(1o\) by exposure to UV light. Shown in Chart 1 is the trans→cis isomerization of \(1o\), which has been suggested to be the thermodynamically stable \(1o\)-isomer. The photo-stationary distribution after exposure to 254 nm light is \(50/46\) \(1c/1o\) as judged by NMR measurements whereas visible light (\(600\) nm, \(-10\) mW/cm\(^2\)) converts the sample to 100% \(1c\) with a time constant of \(~1\) min. By contrast, the time constant for establishment of thermal equilibrium at 23 °C is 124 min. The equilibrium composition is ca. 67/33 \(1c/1o\).

**Chart 1. Structures of photochromic spiropyran 1**

As shown in Figure 1, \(1c\) does not absorb light significantly in the visible region; its longest-wavelength absorption band is at 348 nm. \(1o\) displays absorption in the visible region with the strongest absorption band centered at 512 nm. The absorption spectra of \(1c\) with and without addition of calf-thymus (CT) DNA are virtually superimposable as illustrated in Figure 1 (top panel, 1c), indicating no or very weak interactions between \(1c\) and DNA. The corresponding spectra of \(1o\) are shown in the lower panel. Here, the spectral changes upon addition of DNA are dramatic as seen by comparing the spectra of \(1o\) without DNA (blue line) with that in the presence of DNA (red line). In fact, the spectral perturbation is even stronger since some unbound \(1o\) remains in solution. A spectrum representing 100% DNA-bound \(1o\) (green line) shows that the longest-wavelength band is shifted from 512 nm to 420 nm, i.e., there is a 92 nm shift toward shorter wavelengths upon DNA addition. Furthermore, the band has experienced a ca. 45% hypochromic shift, i.e., a decrease in the absorbance (see Supporting Information for details on the spectral deconvolutions). These observations clearly show that \(1o\) interacts strongly with DNA.

**Figure 1.** Absorption spectra of \(1c\) (top panel) and \(1o\) (lower panel) in the absence (blue lines) and presence (red lines) of calf-thymus DNA. The contribution from DNA to the overall absorption has been subtracted for ease of comparison. Likewise, the contribution from \(1c\) has been subtracted from the spectra of \(1o\) shown in the lower panel. The green line corresponds to a sample of 100% \(1o\) bound to DNA as the contribution from unbound \(1o\) has been corrected for (see Supporting Information for details). The total concentration of 1 was approximately \(1.5\times10^{-5}\) M. The concentration of DNA was \(11.6\times10^{-5}\) M, and the NaCl-concentration of the solution was 8.6×10^{-5} M.

Figure 2 shows the results from flow-oriented linear dichroism (LD) measurements\(^17\) where \(1\) was exposed to alternating UV and visible light irradiation in presence of calf-thymus DNA. The first spectrum was recorded on a sample containing \(1c\) and DNA and shows a weak negative LD signal in the visible, originating from a small fraction of thermally formed \(1o\). UV irradiation of the sample for 5 minutes converted a substantial fraction to the open form \(1o\), and the isomerization process is paralleled by an amplification of the negative LD signal by more than a factor 3. Subsequent exposure to visible light for 5 minutes decreased the LD response to almost the initial value, signaling that the DNA-binding process can be light-switched both ways. Indeed, upon exposure to a second 5 minutes portion of UV light the previously high-amplitude value of the LD signal was nearly recovered, proving that the observed changes in the LD signal are due to a fully reversible, light-controlled DNA-binding process rather than photo-decomposition. As seen in the inset, the bands of the LD spectra virtually coincide with the absorption bands of DNA-bound \(1o\).
The absorption changes observed upon addition of DNA shown in Figure 1 can also be used to roughly estimate the binding constant for 1o (see Supporting Information). The resulting number of ca. \(2 \times 10^6 \text{M}^{-1}\) is not very high, but would be more than sufficient for applications where the difference in binding affinity between 1c and 1o is the key parameter. A comparison between the absorption spectra of 1o recorded in the presence of AT-DNA ([poly(dA-dT)]\(_2\)) and GC-DNA ([poly(dG-dC)]\(_2\)) shows that the binding affinity of 1o increases in the following order: GC-DNA > AT-DNA (see Supporting Information for details).

In conclusion, we have demonstrated the dramatically different DNA-binding properties of the two isomeric forms of a photochromic spiropyran. The closed, non-binding form is activated by UV light to the open form that intercalates the DNA-bases. The open form in turn can be deactivated and dissociated by visible light, making the DNA-binding equilibrium completely tunable by light.

19. As the wavelength shift upon intercalation is larger than the corresponding shift in going from water to chloroform, it is likely that the intercalation process induces a conformational change to a more non-planar structure of 1o compared to solution.

The absorption spectrum is shown for ease of comparison. The total concentration of binding geometries. The angle between the transition moment of the DNA-binding inset shows the LD signal observed for irradiation (red line), and 5 more minutes UV irradiation (black line). The line), 5 minutes UV irradiation (blue line), 5 minutes visible light absorption spectrum of DNA-bound 1o (green line). The negative of the absorption spectrum is shown for ease of comparison. The total concentration of 1 was approximately \(9 \times 10^{-3} \text{M}\). The concentration of DNA was 13.3 \(\times 10^{-4} \text{M}\), and the NaCl concentration of the solution was 8.6 \(\times 10^{-5} \text{M}\).

Figure 2. Flow-oriented LD spectra on a sample of 1 and calf-thymus DNA after the following irradiation sequence: no light exposure (green line), 5 minutes UV irradiation (blue line), 5 minutes visible light irradiation (red line), and 5 more minutes UV irradiation (black line). The inset shows the LD signal observed for 1o + DNA (red line) and the absorption spectrum of DNA-bound 1o (green line). The negative of the absorption spectrum is shown for ease of comparison. The total concentration of 1 was approximately \(9 \times 10^{-3} \text{M}\). The concentration of DNA was 13.3 \(\times 10^{-4} \text{M}\), and the NaCl concentration of the solution was 8.6 \(\times 10^{-5} \text{M}\).
The dramatically different DNA-binding properties of the two isomeric forms of a photochromic spiropyran have been demonstrated, enabling photo-switched DNA-binding. The closed, UV-absorbing form shows no signs of interaction with DNA. Upon UV exposure the spiropyran is isomerized to the open form that binds to DNA by intercalation. The process is fully reversible as the corresponding dissociation process is induced by visible light.
