

CHALMERS

SPEED SENSOR SIMULATOR BOX

Bachelor thesis in Electrical Engineering

HERMANSSON, EMIL
SERTI, TOMAS

Department of Signals and Systems
CHALMERS UNIVERSITY OF TECHNOLOGY
Gothenburg, Sweden 2015

Preface

The thesis work covers 15 credits and has been performed at the Department of Signals and Systems at Chalmers University of Technology. It is the final step in the education of Electrical Engineering, 180 credits. The thesis work took place at Volvo Powertrain where a Speed Sensor Simulator Box was designed during 10 weeks of the spring term 2015.

We would like thank our mentor at school, Manne Stenberg, for his dedication during the project and our supervisor at Volvo Powertrain, Erik Svängård, for making this thesis work possible. We would also like to express our gratitude to our mentor at Volvo Powertrain, Agne Holmqvist, which during the project has given us support, advice and shown great commitment. Furthermore, we would like to thank the remaining employees who contributed with help and support, but also to a good atmosphere at the workplace.

At last, we would like to acknowledge ArduinoTM licenses and thank them for letting us use images of original ArduinoTM boards, under the circumstances that we use the TradeMark sign every time ArduinoTM is mentioned.

Abstract

Volvo is today one of the largest truck manufacturers in the world and an important part of the truck engine is the engine control module. The engine control module is in constant development and needs to be tested regularly. This development takes place at Volvo Powertrain where tests and measurements are performed on engine control modules. Since Volvo Powertrain is in need of a Speed Sensor Simulator Box, the purpose of this thesis work has been to create such a product. The Speed Sensor Simulator Box shall be used at tests and measurements of engine control modules and be able to generate speed signals that mimic the signals being generated from cam- and crankshaft sensors in real truck engines.

The project was performed at Volvo Powertrain where software as well as electronic hardware was designed. The software was developed in Arduino™ and manages the signal generation, while the electronic hardware receives and processes the generated signals. The result was presented in a box that either can run standalone or be controlled by a computer. The Speed Sensor Simulator Box is equipped with a display that shows the current speed and a rotating potentiometer that can adjust the speed. When the unit is controlled by computer, the serial interface is built upon simple menus and the number of functions increases as displacements can be made between the cam- and crankshafts.

Due to time limits, some limitations have been made where the most significant have been included in the project. Focus has been on creating a product that can generate cam- and crank signals with sufficient resolution, signal synchronization and fault injection. Furthermore, the unit should be galvanic isolated from the engine control module and the speed should be presented on a display.

Sammanfattning

Volvo är idag en av världens största lastbilstillverkare och en viktig del i lastbilsmotorn är motorstyrenheten. Motorstyrenheten är i ständigt utveckling och måste regelbundet testas. Denna utveckling sker på Volvo Powertrain där tester och mätningar utförs på motorstyrenheter. Då Volvo Powertrain är i behov av en varvtalssimulatorlåda så har syftet med detta examensarbetet varit att skapa en sådan produkt. Varvtalssimulatorlådan skall användas vid tester och mätningar på motorstyrenheter och kunna generera varvtalssignaler som efterliknar de signaler som genereras från kam- och vevaxelgivare i verkliga lastbilsmotorer.

Projektet utfördes på Volvo Powertrain där mjukvara samt elektronikhårdvara konstruerades. Mjukvaran utvecklades i ArduinoTM och ansvarar för signalgenereringen, medan elektronikhårdvaran tar emot och bearbetar de genererade signalerna. Resultatet presenterades i en låda som antingen kan drivas fristående eller styras via en dator. Varvtalssimulatorlådan är utrustad med en display som visar det aktuella varvtalet och en roterande potentiometer som kan justera varvtalet. När enheten styrs via dator så är det seriella gränssnittet uppbyggt av enkla menyer och antalet funktioner ökar då förskjutningar kan göras mellan kam- och vevaxlarna.

På grund av tidsbrist har vissa avgränsningar gjorts där det mest väsentliga har inkluderats i projektet. Fokus har legat på att skapa en produkt som kan generera kam- och vevaxel-signaler med tillräcklig upplösning, signalsynkronisering och felinjicering. Dessutom skulle enheten galvaniskt avskiljas från motorstyrenheten och varvtalet skulle presenteras på en display.

1. Introduction

1.1. Background

Volvo built its first truck in 1928 and is today one of the largest and leading manufacturers of heavy trucks in the world [1]. A large part of technical development takes place within the Volvo Group Trucks Technology where research, engine development and purchasing activity are important aspects [2].

Within Volvo Powertrain, tests and measurements are performed for the development of ECM's. The ECM is constantly developed to increase performance, safety and improve the environment [2]. Since it controls several functions in the engine, the ECM is an important part of the vehicle and needs to be tested regularly.

One of the fundamental keys to a working ECM is sensing the positions of the cam- and crankshafts. If the ECM does not know the angle of the cam- and crankshafts, it has no idea when to inject fuel to the engine. The ECM gets this information using a set of sensors to detect the position of the cam- and crankshafts as they rotate. These sensors consist of a magnet which detects when a gear tooth passes and a signal is then being generated to the ECM [3]. To facilitate tests and measurements on ECM's, Volvo Powertrain is in need of a Speed Sensor Simulator Box that can generate speed signals similar to those the cam- and crankshaft sensors create.

1.2. Purpose

The purpose is to design a Speed Sensor Simulator Box that can be used at tests and measurements of ECM. The unit should be able to generate speed signals similar to those obtained from real sensors for cam- and crankshafts in truck engines, as well as having the possibility of fault injection. Fault injection can either mean missing teeth or incorrect sync between two signals.

The project consists of both hardware and software and is based on the interaction between them. To generate the desired signals and signal synchronization, software is developed through ArduinoTM. Electronic hardware is built for signal conversion and adaption to the existing ECM's of Volvo Powertrain. A successful product would result in facilitated tests and measurements.

1.3. Delimitations

Due to time limitation, delimitations have been made where focus is on:

- Generating cam and crank speed signals equal to the ones being generated from VR sensors in real engines.
- Sufficient resolution, signal synchronization and fault injection.
- Designing electronic hardware where the signals are processed as well as galvanic isolated from the ECM.
- Creating a box with a panel that contains a display and speed regulation.

1.4. Definition of task

To achieve as good result as possible, the following questions need to be answered:

- How should the signal generation be done?
- Which components are required for the electronic hardware?
 - How should the ECM be galvanic isolation from the circuit?
- How should the software be written to receive the desired signals?
- How should the product be structured?

1.5. Specification

Before the start of the project some specifications were made, see Appendix B and C. These specifications were:

- The signals should be based on a Volvo MD13 engine with EGR.
- The crank signal should consist of 60-2-2-2 gear teeth per crank revolution, which means that one crank revolution consists of 60 gear teeth with two missing gear teeth at three different occasions.
- The cam signal should consist of 6+1 gear teeth per crank revolution, which means that one cam revolution consists of 6 gear teeth plus an extra gear tooth that is used for positioning.
- One cam revolution requires two crank revolutions.
- The engine speed should be adjustable within the range of 10-3600 RPM.
- Signal synchronization and displacements between the cam and crank signals should be able to be selected with an accuracy of $\frac{1}{4}^\circ$, $\frac{1}{2}^\circ$, 1° or 2° . The displacements are made with consideration to the synchronized signal, which has a cam displacement of $\frac{1}{2}^\circ$.
- Engine speed in RPM should be demonstrated on a display.

2. Technical background

2.1. Cam- and crankshaft

An important part of the cam mechanism is the camshaft where a rotating metal shaft converts rotating motions into reciprocating motions. The rotating shaft has one or more lobes that control cam followers as they rotate [4]. The lobes are usually circular with an extra convex side which makes them push and return the cam followers as the shaft rotates, see Figure 2.1.1. A cam follower can either be a sliding surface or a roller.

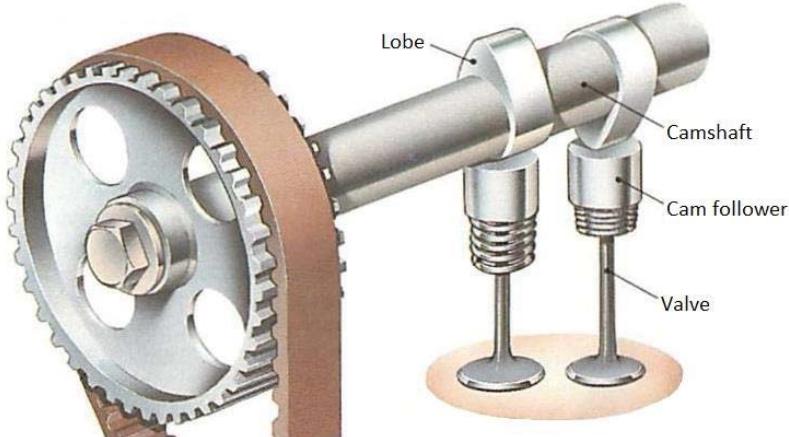

Figure 2.1.1: The camshaft [5].

Camshafts are often used when linear motions are desired, e.g. in regulating valves. As the camshaft rotates, the intake and exhaust valves are opened and closed by the lobes in time with the motion of the piston. For the valves to open at the right pace and at the right angle, it is required that the camshaft is synchronized with the crankshaft [6].

The crankshaft, which basically is the opposite of the camshaft, converts reciprocating motions into rotating motions and is often used to drive a wheel [7]. It is comprised of a long piece of metal in a specific shape and consists of a shaft with one or more crankpins that are connected to a piston rod. The piston rod is further connected to a piston and as the piston moves back and forth, the rod provides rotating motions to the crankshaft. The piston is located inside a cylinder and the volume that is created between the piston and the cylinder head is called combustion chamber. During combustion process, pressure is increased in the chamber and a force is generated which causes movement in the piston and thereby the crankshaft [8]. At one end of the crankshaft, a flywheel is attached whose purpose is to store the energy from particular firings. This is for the engine to run more smoothly [9]. Figure 2.1.2 shows an overview of the crankshaft.

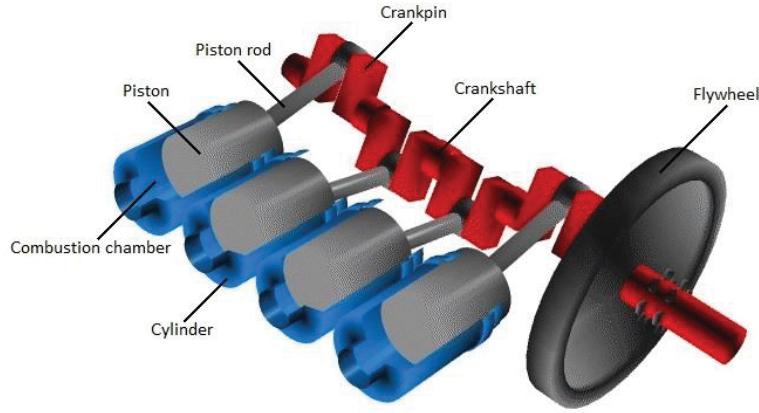

Figure 2.1.2: The crankshaft [8].

In an engine, the timing between the valves and the pistons is critical. It is important that the intake and exhaust valves are opened and closed at the right time; otherwise it could lead to the engine running badly or self-destruction when the valves and the pistons make contact [10]. The cam- and crankshafts are connected to each other by either gear transmission, or by being connected via a belt or a chain, see Figure 2.1.3.

In a four-stroke engine, two complete crankshaft revolutions are made per four-stroke cycle. During this time, the valves are opened and closed only once. Since the valves are operated by the camshaft, the camshaft completes only one revolution per cycle. Thereby, the camshaft is rotating at half the speed of the crankshaft [10].

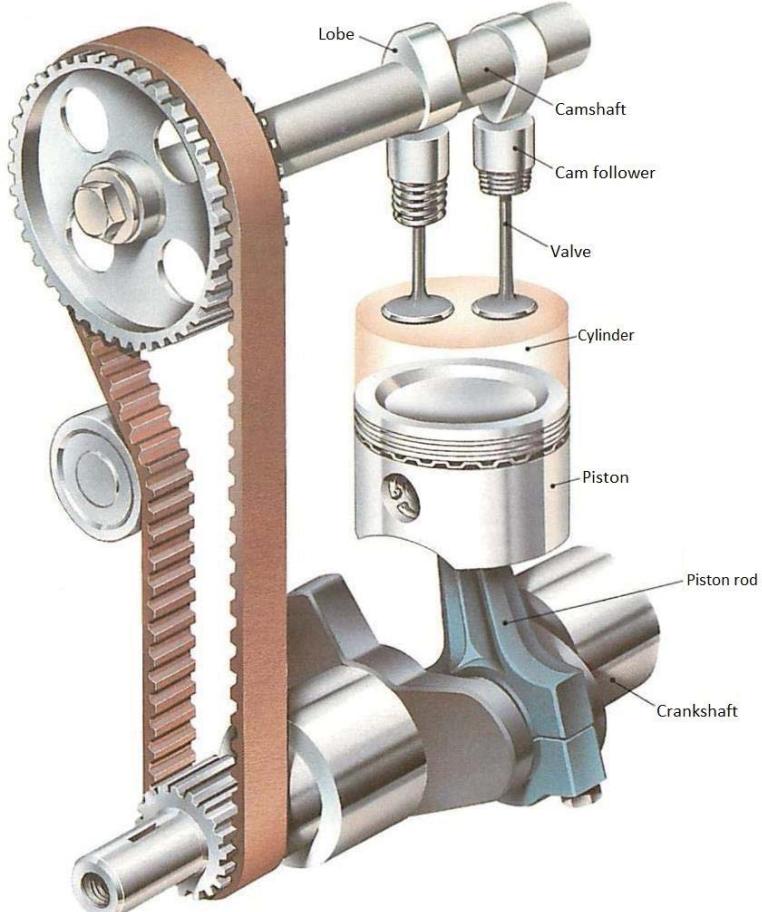

Figure 2.1.3: The cam- and crankshafts connected by a belt [5].

2.2. Variable reluctance sensor

To know the angle positions of the cam- and crankshafts in a truck engine, it is required that the ECM receives the information. This information is given by one or more sensors, where one of the most common types is the VR sensor.

The VR sensor is built of a permanent magnet with a wire wound around it. Current is induced when the ferrous material from a gear tooth passes the magnet. Since the magnetic field is altered when this happens, it leads to an electrical voltage. When the gear tooth moves further away from the magnetic field, the voltage gets an opposite flux. This leads to a time-varying sinusoidal signal that the ECM processes [11], see Figure 2.2.1.

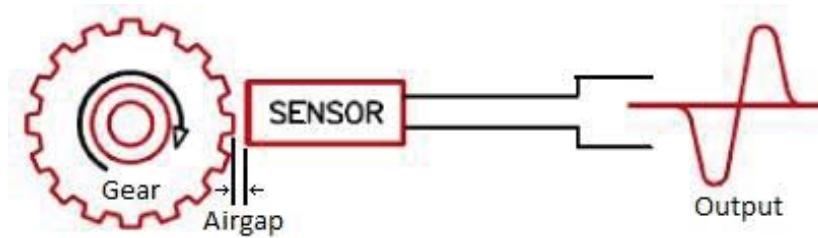

Figure 2.2.1: VR sensor detecting a gear tooth [12].

The ECM transduces the sinusoidal signal into a digital signal that can be more easily read than an analog signal. Each period of the signal corresponds to a gear tooth and with the help of an evaluation from the ECM, the engine speed in RPM as well as the information about where in the cycle the engine is at the time can be determined [11].

2.3. SIMetrix

SIMetrix is a simulation program where analog and mixed signals can be simulated. The program contains functions which allow the user to build up own electrical circuits to get an idea of how they could act in reality. The ability to simulate in this way makes it easier for the user to test circuits and knowing which components that might be appropriate. From the simulations it is possible to get analog and mixed signals which can be displayed in either waveforms or different sweep [13].

2.4. ArduinoTM

ArduinoTM is an open-source hardware microcontroller board which is intended to make the use of electronics more accessible. The hardware consists of a simple circuit design, while the software consists of a programming language, a compiler and a boot loader running on the board [14].

When using ArduinoTM, interactive objects can be developed. However, it can also be used to receive input signals from different switches and sensors, as well as controlling lights, motors and other physical outputs. ArduinoTM projects can either be standalone or communicate with software running on the computer [15].

2.4.1. Arduino™ software

An Arduino™ project or code is called a “sketch” and is written in either C or C++. In this project the programming is performed in Arduino™ IDE, which is a cross-platform application written in Java. It is designed to easily introduce newcomers that usually are unfamiliar with software development [14].

To make input and output operations much easier, the Arduino™ IDE uses a software library called “Wiring”, which is an open-source programming framework [16]. As a result of this, the user only needs to define the following two functions to make an executable program:

- `setup()` – a function that can initialize settings and that runs once at the start.
- `loop()` – a function that runs repeatedly [14].

2.4.2. Arduino™ hardware

The Arduino™ boards consist of Atmel AVR microcontrollers with complementary components that facilitate programming as well as integration with other circuits. Different versions of Arduino™ boards have been created where the Arduino™ Uno and the Arduino™ Mega are the most common ones [14]. In this project an Arduino™ Uno is used.

The Arduino™ Uno board uses an Atmega328 chip from the megaAVR series. It has 14 digital I/O pins where 6 of them can be used as PWM outputs. In addition, the board has 6 analog inputs, a 16 MHz ceramic resonator, a reset button, a USB connection and a power jack where 7-12 V are recommended as input voltage [17]. Furthermore, the board also has outputs pins that deliver 5 V, 3.3 V and ground, see Figure 2.4.2.1.

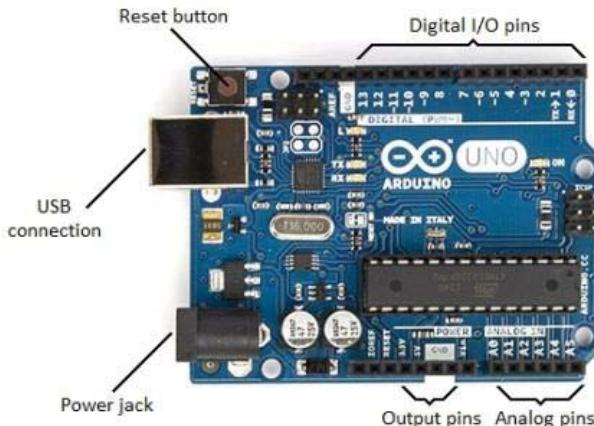

Figure 2.4.2.1: Arduino™ Uno [17].

2.4.3. Druid4Arduino

As previously mentioned in section 2.4, Arduino™ projects can either be standalone or communicate with software running on the computer. An example of such software is Druid4Arduino, which is a program that can interact with SerialUI-based Arduino™ projects through a simple GUI with menus. By connecting a USB-A cable to the Arduino™ board, Druid4Arduino will connect to the Arduino™ project and create the commands and menus defined in the sketch [18].

2.5. Hardware

This section describes the electronic hardware that is used in the project. To know how the different components are connected to each other, see Appendix A.

2.5.1. Potentiometers

A potentiometer is an adjustable resistance. The circuit contains two potentiometers of type 3540S-1-103L which has a resistance of $10\text{ k}\Omega$ [19]. One is used for regulating the backlight of the LCD and the other is used for setting the RPM of the signals. By turning a sliding contact back and forth, the resistance can be regulated. Based on the voltage level being controlled by the resistance, an analog value is read into the ArduinoTM [20]. This value determines the RPM and prints it on the display.

2.5.2. Liquid Crystal Display

The LCD being used is an ATM1602B [21]. It can fit 2x16 characters and has a blue backlight which is adjustable by a potentiometer.

The only thing shown on the display is the actual RPM. As the backlight, the RPM value is also adjustable by a potentiometer. Since revolutions over 3600 RPM are not needed, there is no way to exceed this value. In other words, the RPM showed on the display stops at 3600 RPM even if the potentiometer is being rotated.

2.5.3. Transformers

The circuit contains two transformers of type THD 6235.0 [22]. Through electromagnetic induction, a transformer converts electrical energy between current- and voltage levels [23].

One transformer is being used for the cam signal and the other is being used for the crank signal. The secondary winding of each transformer is connected to the ECM which receives and processes the generated signals. The transformers galvanic isolate the ECM from the rest of the circuit.

2.5.4. DC/DC-converter

A DC/DC-converter converts a source of DC from one voltage level to another [24]. The type being used is a TEN 5-2422WI from Traco Power and its purpose is to power the circuit as well as the ArduinoTM board in standalone mode [25]. The DC/DC-converter can handle input voltages within the range of 9-36 VDC and provides an output voltage of ± 12 VDC. This is a safety for other components since it only supplies 12 V even if higher or lower voltages are being supplied.

2.5.5. Operational amplifiers and buffers

An operational amplifier and two buffers are contained in the circuit. The operational amplifier is a voltage amplifier of type LM324N and it contains four operational amplifiers in the same device [26]. However, only two operational amplifiers are being used, one for the cam signal and one for the crank signal.

The buffers used are of type BUF634P [27]. As the operational amplifiers, one buffer is being used for the cam signal and the other is being used for the crank signal.

The operational amplifier and the buffer are intended to work as a voltage follower in order to increase the power to the transformer, see Figure 2.5.5.1.

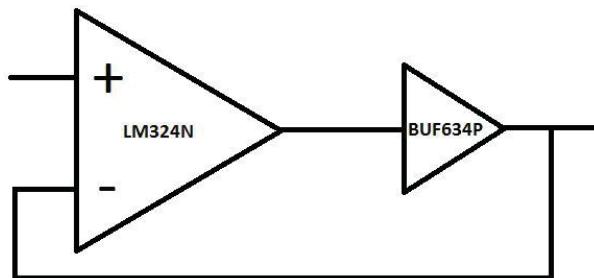

Figure 2.5.5.1: The voltage follower.

3. Implementation

3.1. Preliminary learning

To be able to create a Speed Sensor Simulator Box that generates cam and crank signals, it was necessary to know how the cam- and crankshafts operate and interact. Through the mentor at Volvo as well as research on the internet, this information was given in both texts and figures.

Since the idea behind the project was to generate the signals through ArduinoTM, a lot of knowledge needed to be obtained within that area. This was mainly done by a set of tutorials where fundamental knowledge was declared [28]. Furthermore, a lot of good information and examples were given at the homepage of ArduinoTM [29]. During the time of learning, practical tasks were performed where programming code were compiled and uploaded to the ArduinoTM board.

After further research on the internet as well as a proposal from the mentor at Volvo, an appropriate open-source program code called Ardu-Stim was found [30]. It is an ArduinoTM Uno based cam and crank wheel pattern generator developed to test how different ECM's respond to cam and crank signals. As this was free to use and modify under the terms of the GNU General Public License, major parts of the preliminary learning was spent on reviewing the code in order to be able to modify the parts that was necessary for the project [31].

3.2. Simulations

To be able to determine which components the electronic hardware should consist of, the program SIMetrix was used to simulate circuits in theory. As the signals from the ArduinoTM board are digital and within the range of 0-5 V, similar signals tried to be created. Since Ardu-Stim transmits cam- and crank signals on one pin each, a source that generates a 5 V digital signal was used. The signal was further connected to an operational amplifier used as a voltage follower to get lower output impedance and minimizing the risk of interference without affecting the voltage level of the signal.

In order to get galvanic isolation between the ECM and the rest of the circuit, a transformer was connected the output of the voltage follower, see Figure 3.2.1. Galvanic isolation means that the two sides are being isolated from each other to prevent undesired currents from flowing between the ECM and the signals of the circuit. [32]. Another benefit is that the transformer lowers the signal and creates the desired zero-crossing, which means that the signal is symmetrical around 0 V. Simulation 1 in Results shows the result of the simulated circuit with one source.

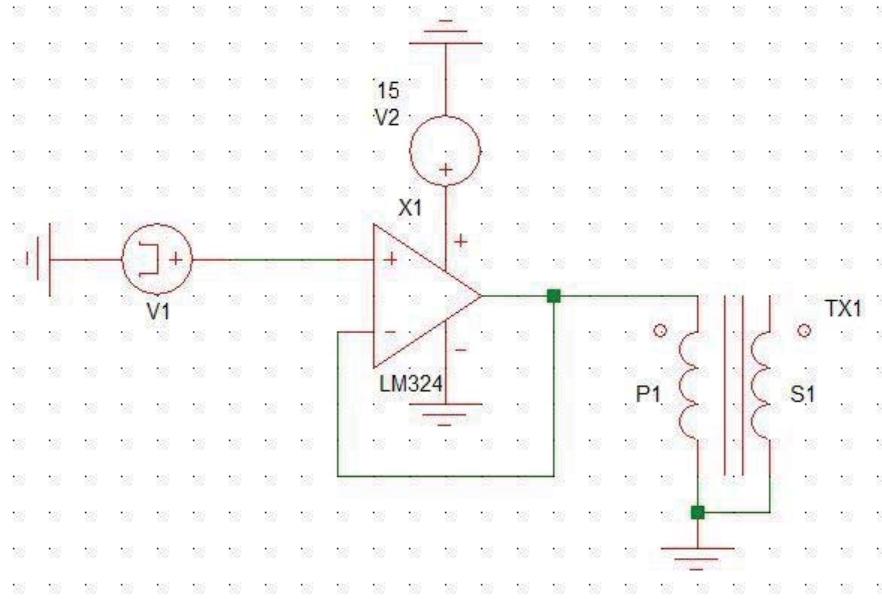

Figure 3.2.1: The simulated circuit with one source.

To make the generated signals more similar to the signals being generated from VR sensors in real engines, an additional source that generates a 5 V digital signal was added. Having two sources opens the possibility of a third voltage level between 0 V and 5 V. When one source is high and one source is low, the voltage level will be at 2.5 V. This voltage level corresponds to “idle” and occurs between different gear teeth as well as when a gear tooth is missing. In the previous circuit where only one source were used, this “idle” level did not exist and a missing gear tooth would simply be registered as 0 V, see Figure 3.2.2.

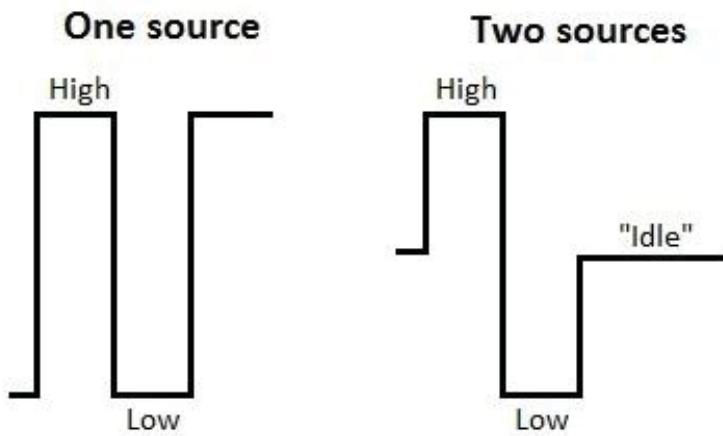

Figure 3.2.2: Signals with one respectively two sources.

Furthermore, an adder with two resistances was used to merge the two signals, see Figure 3.2.3. Simulation 2 in Results shows the result of the simulated circuit with two sources.

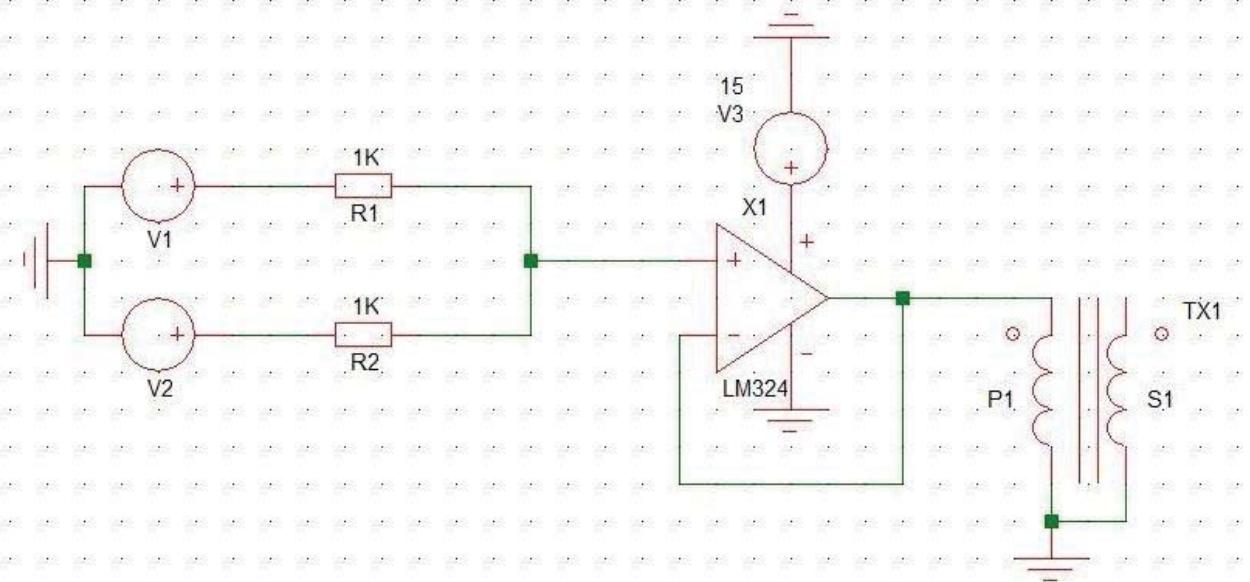

Figure 3.2.3: The simulated circuit with two sources.

3.3. Software

3.3.1. Ardu-Stim

The software is based on Ardu-Stim, which is an open-source program code developed to test how different setups respond to signals. The cam and crank wheel pattern generator supports over 30 different wheel patterns up to 12 000 “virtual” RPM and is user controlled via a USB to serial interface with Druid4Arduino [30]. Each wheel pattern consists of various amounts of gear teeth and corresponds to a respective type of vehicle. Furthermore, the code is constructed of a header file and a set of sub-files that processes the wheel patterns as well as the Serial UI.

3.3.2. Signal generation

The wheel patterns are stored in arrays of different sizes, depending on the structure of a vehicle type. Each value, or edge, in the array corresponds to an 8 bit binary number that are transmitted to PORTB of the Arduino™ board. PORTB are responsible for pins 8-13 and depending on the received value, different states are defined for these output pins.

In the Ardu-Stim original code, pin 8 transmits the crank signal and pin 9 transmits the cam signal. Pin 8 corresponds to bit0 of PORTB and pin 9 corresponds to bit1 of PORTB. The states of these pins depend on the value of the corresponding bit. When a pin receives the binary value 1, a high state is generated. Respectively, when a pin receives the binary value 0, a low state is generated. Table 3.3.2.1 shows how output pins are defined.

Table 3.3.2.1: Definition of output pins.

Decimal value	Binary value	Pin 8	Pin 9	Crank signal	Cam signal
0_{10}	$0000\ 0000_2$	Low	Low	Low	Low
1_{10}	$0000\ 0001_2$	High	Low	High	Low
2_{10}	$0000\ 0010_2$	Low	High	Low	High
3_{10}	$0000\ 0011_2$	High	High	High	High

As previously mentioned, a circuit with two sources was simulated in order to make the generated signals more similar to real signals. By adding a high signal with a low signal, a third voltage level could be achieved. This voltage level corresponds to “idle” and occurs between different gear teeth as well as when a gear tooth is missing, see Figure 3.2.2.

To be able to create this signal with Ardu-Stim, the cam and crank signals needed to be transmitted on two output pins each. Therefore, this was solved by transmitting the crank signal on pins 8-9 and transmitting the cam signal on pins 10-11. According to the same structure as before, pins 8-9 corresponds to bit0-1 of PORTB and pins 10-11 corresponds to bit2-3 of PORTB. When a pin receives the binary value 1, a high state is generated. Respectively, when a pin receives the binary value 0, a low state is generated. Table 3.3.2.2 shows how output pins are defined as well as how the cam and crank signal are constructed. See Construction of wheel patterns in Results for more information.

Table 3.3.2.2: Definition of output pins as well as construction of cam and crank signals.

Decimal value	Binary value	Pin 8	Pin 9	Pin 10	Pin 11	Crank signal	Cam signal
0_{10}	$0000\ 0000_2$	Low	Low	Low	Low	Low	Low
1_{10}	$0000\ 0001_2$	High	Low	Low	Low	Idle	Low
2_{10}	$0000\ 0010_2$	Low	High	Low	Low	Idle	Low
3_{10}	$0000\ 0011_2$	High	High	Low	Low	High	Low
4_{10}	$0000\ 0100_2$	Low	Low	High	Low	Low	Idle
5_{10}	$0000\ 0101_2$	High	Low	High	Low	Idle	Idle
6_{10}	$0000\ 0110_2$	Low	High	High	Low	Idle	Idle
7_{10}	$0000\ 0111_2$	High	High	High	Low	High	Idle
8_{10}	$0000\ 1000_2$	Low	Low	Low	High	Low	Idle
9_{10}	$0000\ 1001_2$	High	Low	Low	High	Idle	Idle
10_{10}	$0000\ 1010_2$	Low	High	Low	High	Idle	Idle
11_{10}	$0000\ 1011_2$	High	High	Low	High	High	Idle
12_{10}	$0000\ 1100_2$	Low	Low	High	High	Low	High
13_{10}	$0000\ 1101_2$	High	Low	High	High	Idle	High
14_{10}	$0000\ 1110_2$	Low	High	High	High	Idle	High
15_{10}	$0000\ 1111_2$	High	High	High	High	High	High

The patterns are stored in a sub-file called “wheel_defs.h”. In order to get signal synchronization and correct displacements between the two signals, the pattern size is crucial. To determine the size of this array, the distance between each gear tooth as well as the amount of edges per gear tooth needs to be calculated. Furthermore, the array size is used to calculate the “RPM scaler”, which is an important factor as it helps deciding the prescaler of a timer, see Calculations in Results. The prescaler defines the clock frequency of a timer and thus, it sets the time period of the signal with consideration to the chosen RPM.

3.3.3. Interrupt service routines and Timers

Many Arduino™ sketches run the main code under the “loop()”-function. This is called “polling” and is a quite expensive method for the microcontroller. Another method is to use interrupt service routines, which is good for solving timing problems and making things happen automatically [30].

At the time an interrupt occurs, an interrupt signal is sent to the microcontroller. The interrupt signal marks the event that requires immediate attention and demands the processor to stop the current program in order to make time for the program associated with the interrupt. This program is called interrupt service routine, or sometimes interrupt handler [33]. Before executing the code in an ISR, the processor saves its execution state. In this way, it can return to whatever it was doing after running an ISR [34].

Since ISR's requires less processor time as well as minimizes the risk for missing data between readings, they are cleverly used in Ardu-Stim. The most important ISR is the “ISR(TIMER1_COMPA_vect)” as it executes the code that outputs the signals. It is called when an output compare match interrupt occurs for Timer1 [35].

Timer1 is one of three hardware timers available on the chip. It is a 16 bit hardware timer controlled by the Timer1 library that was developed to quickly and easily set the PWM period or frequency of a timer. As previously mentioned, the clock frequency is defined through a prescaler [36]. The prescaler reduces the clock frequency by integer division as it divides the clock frequency by a value. Timer1 of the ArduinoTM Uno board has a clock speed of 16 MHz which is defined by setting the prescaler to either 1, 8, 64, 256 or 1024, see Table 3.3.3.1 [36].

Table 3.3.3.1: Clock frequency defined by prescaler value.

Prescale	Time per counter tick	Max Period
1	0.0625 µs	8.192 ms
8	0.5 µs	65.536 ms
64	4 µs	524.288 ms
256	16 µs	2097.152 ms
1024	64 µs	8388.608 ms

3.3.4. Potentiometer and LCD

As previously mentioned, a potentiometer is used to control the RPM in standalone mode. It is connected to analog pin 0 (A0) of the ArduinoTM board. Based on the voltage level that is controlled by the resistance value of the potentiometer, an analog value between 0-5 V is converted to a digital value between 0-1023 and read into the ArduinoTM board. In order to determine the correct RPM, this value is multiplied by 4 to be able to get resolutions up to 4096 RPM. However, a limit has been added at 3600 RPM since higher revolutions are not needed. The analog value is sent into a function that calculates an appropriate prescaler and defines the clock speed, which decides how often the pattern array should be read. With other words, it defines the time period of the signal.

Furthermore, the analog value is printed on the LCD to show the current RPM. To react quickly to changes and without blinking, the LCD is being updated every 100 ms. This part is being handled by the “loop()”-function, which only controls the LCD as well as the Serial UI. Since both the LCD and the Serial UI are being controlled by the “loop()”-function, only one of them can run at the same time. As soon as the program Druid4Arduino is opened, the program will focus on the Serial UI and the LCD as well as the potentiometers will be deactivated. When Druid4Arduino is closed, the components will be activated once again.

3.3.5. Serial UI

To be able to build the Serial UI for Druid4Arduino, the library “SerialUI.h” is needed. It is useful when menus, sub-menus or command executions are requested. The Serial UI is being controlled by the “loop()”-function. However, the actual code is presented in a sub-file called “serialmenu.h”.

The menus, texts and command executions that are shown in Druid4Arduino are created through several callbacks. A callback is a function used by the SerialUI library when a message arrives. The message handling code is placed in a function and the library is told to call it back when it receives the corresponding message [37], see Figure 3.3.5.1.

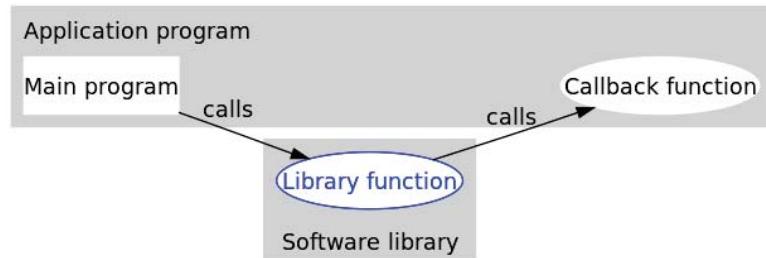

Figure 3.3.5.1: Main program calling a callback function [38].

When opening Druid4Arduino, the layout is comprised of a menu with several buttons, see Serial UI in Results.

3.4. Measurements

Major parts of the signal generation are based on tests and measurements. By documents obtained from Volvo, attempts have been made to generate signals similar to the ones being generated from sensors in real engines, see Figure 3.4.1 from Appendix C. Although the signals are sinusoidal, it has not been necessary to generate this type of signals. The importance has been to create a signal with a quick zero-crossing between the maximum and minimum amplitude. Since the ECM converts the sinusoidal signal to a digital signal, this has been done with a digital signal directly.

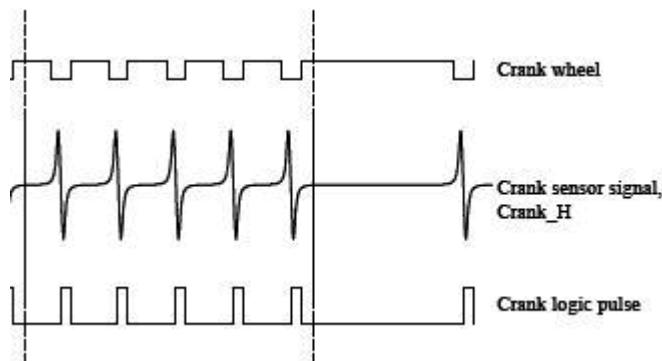

Figure 3.4.1: Generated signals from obtained documents.

The signals have been generated through Arduino™ and the output pins have been carefully examined in an oscilloscope of type Tektronix TDS3014. Since Ardu-Stim transmits the crank signal on pin 8 and the cam signal on pin 9, measurements were performed in order to see that the intended signals were received, see Measurement 1 in Results.

After this was verified, the creation of new wheel patterns began. To be able to transmit the signals on two pins each, two more pins needed to be initialized as output pins. The decision was to transmit the crank signal on pins 8-9 and the cam signal on pins 10-11. As SIMetrix predicted, resistances were needed in order to create the adder that merges the signals. Measurement 2 in Results shows the result of the measured signal with two sources.

When the correct wheel patterns had been created, the simulated circuit was built and the electronic hardware was tested in reality. After tests and verifications, some small modifications were made compared to the simulated circuit in SIMetrix. Since the ECM affects the circuit when it connects to the transformer, a buffer was connected to the operational amplifier as a feedback to increase the power to the transformer, see Figure 2.5.5.1. Test and verification in Results shows the final results.

3.5. Product structure

The product is made of a plastic box with a metal lid. Inside the box is the location of the Arduino™ Uno board as well as the electronic hardware that processes the generated signals, see Figure 3.5.1.

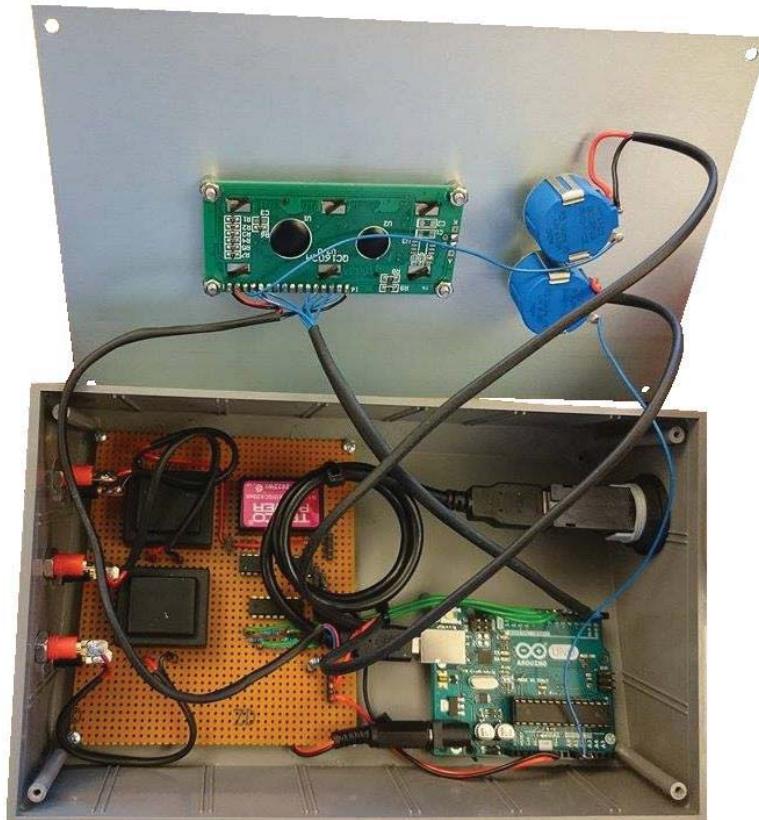

Figure 3.5.1: The inside of the box.

The Speed Sensor Simulator Box can be used in two modes; it can either run standalone or run by computer. Two potentiometers and a LCD is attached to the metal lid for standalone mode, see Figure 3.5.2. When in standalone mode, the LCD shows the generated speed in RPM while one potentiometer controls the speed and the other potentiometer controls the backlight of the LCD. The maximum RPM is 3600 and the potentiometer that controls the RPM increases with a resolution of 4 RPM at a time. However, when the unit runs by computer the RPM can be chosen with a resolution of 1 RPM.

Figure 3.5.2: The LCD and the potentiometers.

By connecting the unit to a computer via a USB-A cable, access to connect with Druid4Arduino is given. By opening the program, the LCD and the potentiometers that are used at standalone mode will be deactivated.

The benefit of running the unit by Druid4Arduino is the increased number of features. In addition to adjusting the speed, the user can also select different wheel patterns where the cam signal is displaced in relation to the crank signal. By closing Druid4Arduino, the LCD and the potentiometers will be activated once again.

Even though the unit is energized by the computer through the USB-A cable, supply voltage and ground needs to be connected to the box to power the electronic hardware. As the DC/DC-converter can receive voltages within the range of 9-36 V, this is a requirement for acceptable supply voltage. Outputs are also available for the ECM which receives and processes the generated cam- and crank signals, see Figure 3.5.3.

Figure 3.5.3: In- and outputs of the unit.

4. Alternative solutions

The project can be done in several ways. The mentor at Volvo had two suggestions of solutions, where:

- The first alternative was to use a pure microprocessor solution that together with an appropriate constructed circuit board generates and processes the cam and crank signals. A suggestion of microprocessor was Arduino™, since it is user-friendly and it is quite easy to define states for input and output pins.
- The second alternative was to use a memory with a parallel output that clocks out the content with a controllable PLL to a DAC. In this way, the timing of single or combined signals can be controlled with great precision.

The project was performed with the microprocessor solution, which turned out to be working great. The signal generation could probably be programmed in several ways, however, the solution that Ardu-Stim used was well thought out and easy to understand.

Furthermore, the selection of electronic hardware could have been done differently. Instead of galvanic isolating the circuit with a transformer, another solution could have been to use an optocoupler. Except that the optocoupler galvanic isolates the circuits, this device also prevents electrical disorders from spreading through electrical systems [39].

However, since the transformer was tested and turned out to process the signals well, this component was chosen.

5. Results

5.1. Simulations results

5.1.1. Simulation 1

The following result refers to Figure 3.2.1 where a circuit with one source has been simulated, see Figure 5.1.1.1.

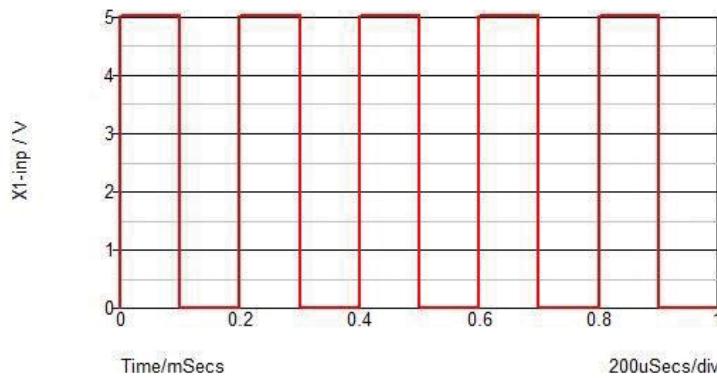

Figure 5.1.1.1: Simulation result from a circuit with one source.

5.1.2. Simulation 2

The following result refers to Figure 3.2.3 where a circuit with two sources has been simulated. The result is divided into three images where the first represents source 1 (Figure 5.1.2.1), the second represents source 2 (Figure 5.1.2.2) and the third represents the merged signal from the two sources (Figure 5.1.2.3).

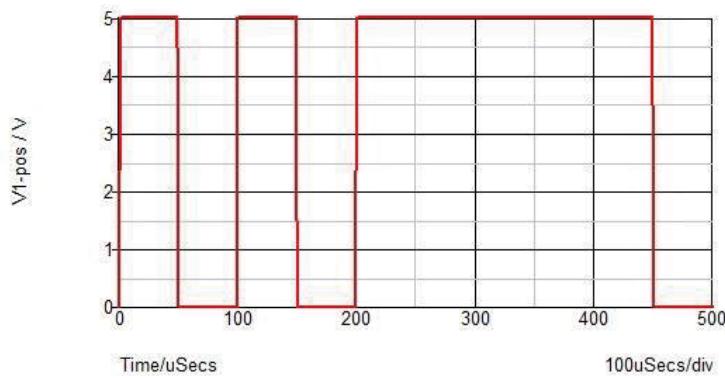

Figure 5.1.2.1: Simulation result from source 1.

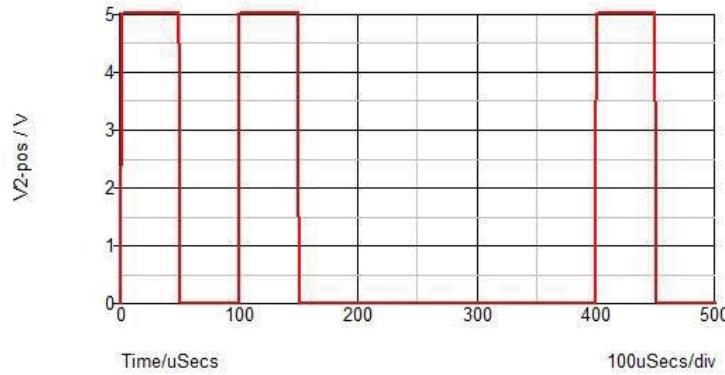

Figure 5.1.2.2: Simulation result from source 2.

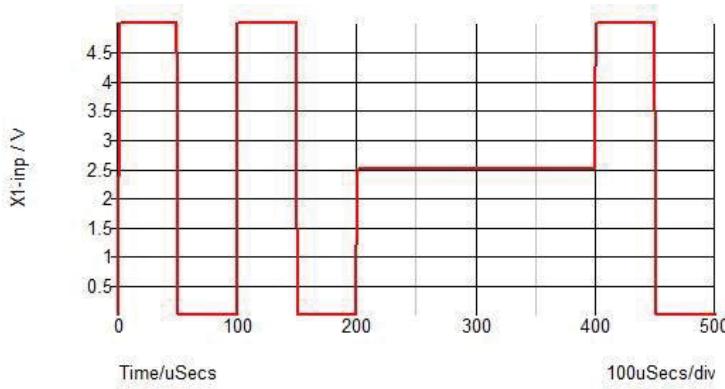

Figure 5.1.2.3: Simulation result from the merged sources.

5.2. Software results

5.2.1. Calculations

In order to get signal synchronization and correct displacements between the cam- and crank signals, some calculations had to be made. To determine the size of the wheel pattern array, the distance between each gear tooth was calculated according to formula (1).

$$\text{Tooth angle} = \frac{\text{Degrees per revolution}}{\text{Number of gear teeth}} = \frac{360^\circ}{60 \text{ gear teeth}} = 6^\circ \quad (1)$$

This means that a gear tooth occurs every 6° . However, to be able to calculate the size of the wheel pattern array, the amount of edges per gear tooth needed to be calculated. Since the largest accuracy of a displacement is $\frac{1}{4}^\circ$, it needs the most edges to be described. This was done through formula (2).

$$\text{Edges/gear tooth} = \frac{\text{Tooth angle}}{\text{Displacement}} = \frac{6^\circ}{\frac{1}{4}^\circ} = 24 \quad (2)$$

By this result, it means that it takes 24 edges in the wheel pattern array to create a 6° gear tooth that has the possibility to be displaced $\frac{1}{4}^\circ$. Since one crank revolution consists of 60 gear teeth and two crank revolutions are required per cam revolution, a total number of 120 gear teeth are needed in the wheel pattern array. This gives the following size of the array, see formula (3):

$$\text{Array size} = \text{Edges/gear tooth} \cdot \text{number of gear teeth} = 24 \cdot 120 = 2880 \text{ edges (3)}$$

To create patterns with smaller accuracy, fewer edges are needed. However, since the calculated pattern size of 2880 edges can create all the wanted patterns of $\frac{1}{2}^\circ$, 1° and 2° , the same size were used for all displacements.

As mentioned in section 3.3.2, the “RPM” scaler” that helps deciding the prescaler of a timer needed to be calculated. This was done through formula (4):

$$\text{RPM scaler} = \frac{\text{Total number of edges}}{\text{Wheel array ratio}} = \frac{2880}{240} = 12 \text{ (4)}$$

The wheel array ratio is predetermined by the creator of Ardu-Stim. In wheel patterns where only one crank revolution occurs, this value is set to 120. In wheel patterns where two crank revolutions occur (typically patterns with a cam signal); this value is set to 240.

5.2.2. Construction of wheel patterns

As calculated in section 5.2.1, each wheel pattern is defined through 2880 edges where 24 edges correspond to one gear tooth. Table 3.3.2.2 shows the different choices of values that are available for each edge. Since some values gives the same output signals, as well as every alternative not being needed, the following values have been used in the created wheel patterns:

- 0 – When both signals are low.
- 1 – When crank signal idles and cam signal is low.
- 4 – When crank signal is low and cam signal idles.
- 5 – When both signals idle.
- 7 – When crank signal is high and cam signal idles.
- 12 – When crank signal is low and cam signal is high.
- 13 – When crank signal idles and cam signal is high.
- 15 – When both signals are high.

The displacements are made with consideration to the synchronized signal, which has a cam displacement of $\frac{1}{2}^\circ$. Since each value in the array corresponds to $\frac{1}{4}^\circ$, a displacement of $\frac{1}{2}^\circ$ corresponds to two values. Table 5.2.2.1 shows a number of created gear teeth.

Table 5.2.2.1: Created gear teeth.

Since the cam teeth only occur during missing crank, it does not affect the crank teeth array description. Therefore, the same crank teeth array description is used in every wheel pattern. However, the cam signal varies from pattern to pattern. As seen in Table 5.2.2.1, the cam teeth array descriptions have displacements in relationship to each other, where every edge corresponds to a displacement of $\frac{1}{4}^\circ$.

5.2.3. Serial UI

This section presents the appearance of the Serial UI in Druid4Arduino, see Figure 5.2.3.1. The following information applies to each button:

- **Information** – Gives the user information about the product as well as the currently selected wheel pattern.
 - **Set RPM** – A command execution to set the wanted RPM. If the selected RPM is not within the range of 10-3600 RPM, an error message occurs.
 - **Sync** – Synchronizes the cam and crank signals. However, this is a cam displacement of $\frac{1}{2}^\circ$ and other displacements are done with consideration to this.
 - **$\frac{1}{4}$ degree** – Displaces the cam signal $\frac{1}{4}^\circ$ in relation to the crank signal.
 - **$\frac{1}{2}$ degree** – Displaces the cam signal $\frac{1}{2}^\circ$ in relation to the crank signal.
 - **1 degree** – Displaces the cam signal 1° in relation to the crank signal.
 - **2 degrees** – Displaces the cam signal 2° in relation to the crank signal.

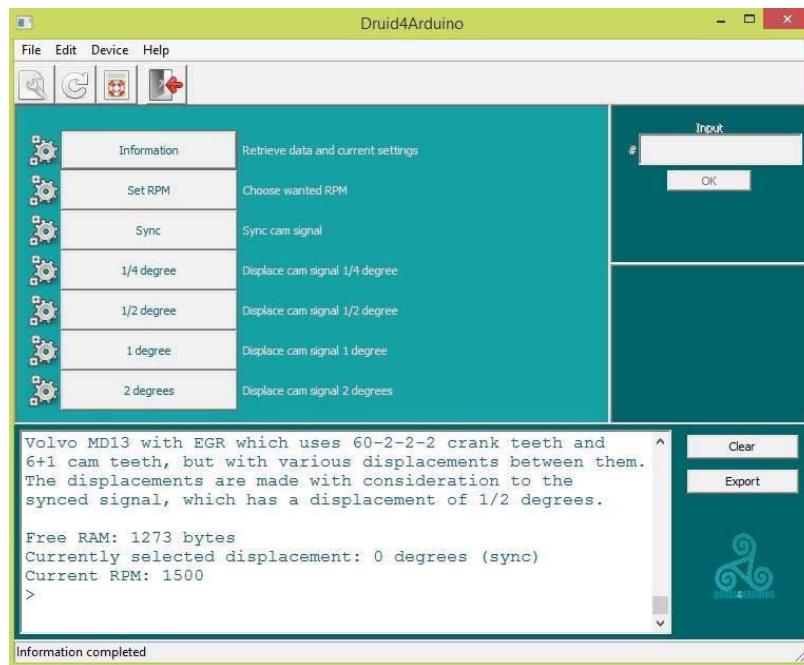

Figure 5.2.3.1: Druid4Arduino layout.

5.3. Measurement results

5.3.1. Measurement 1

The following result refers to the measurements made on the original Ardu-Stim program where the cam- and crank signals were transmitted on one pin each. The cam- and crank signals have the same appearance; however, Figure 5.3.1.1 only shows the crank signal.

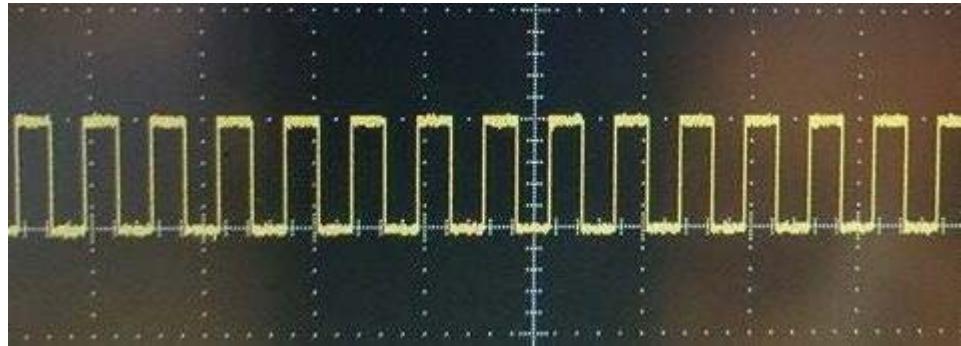

Figure 5.3.1.1: The crank signal transmitted on one pin.

5.3.2. Measurements 2

The following result refers to the measurements made on the modified Ardu-Stim program where the cam- and crank signals were transmitted on two pins each. The cam- and crank signals have the same appearance; however, Figure 5.3.2.1 only shows the crank signal.

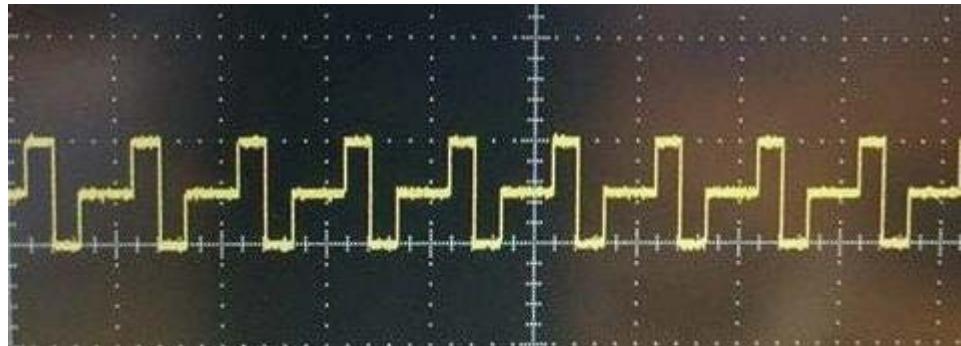

Figure 5.3.2.1: The crank signal transmitted on two pins.

5.4. Test and verification

When the correct wheel pattern had been created, the cam- and crank signals were connected to the electronic hardware. After connecting the ECM to the circuit, measurements were made to test and verify that the unit worked as intended. The result was a product that worked in standalone mode as well as controlled by a computer. In both methods, the signals appeared as they should, see Figures 5.4.1-5.4.5.

At last, the Speed Sensor Simulator Box was connected to an ECM controlled by a computer and it was confirmed that the generated RPM was received.

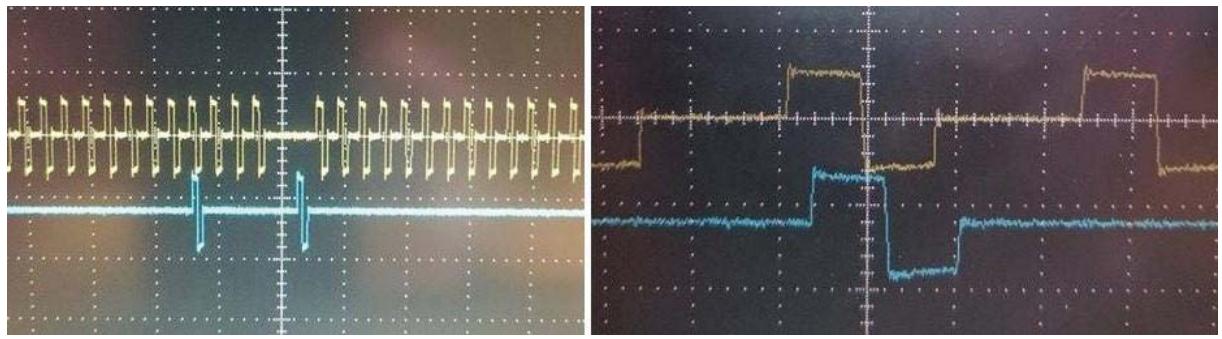

Figure 5.4.1: The cam- (blue) and crank (yellow) signals in sync, which has a displacement of $\frac{1}{2}^\circ$.

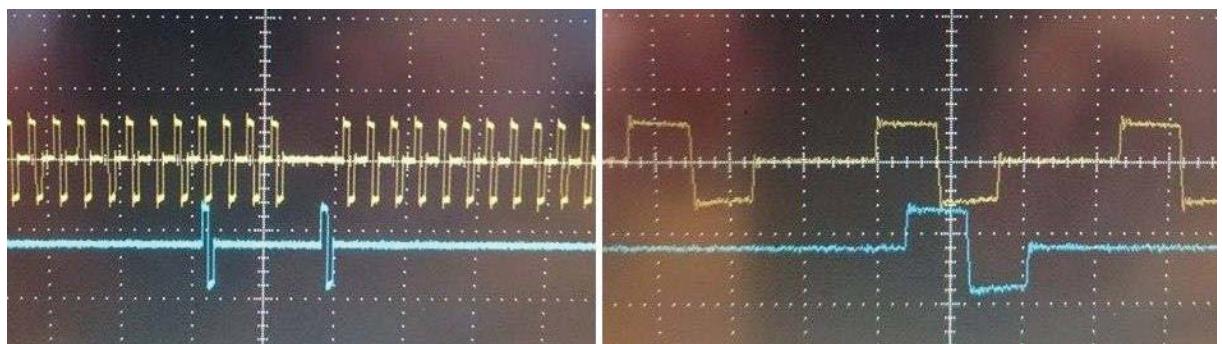

Figure 5.4.2: The cam- (blue) and crank (yellow) signals with a displacement of $\frac{1}{4}^\circ$.

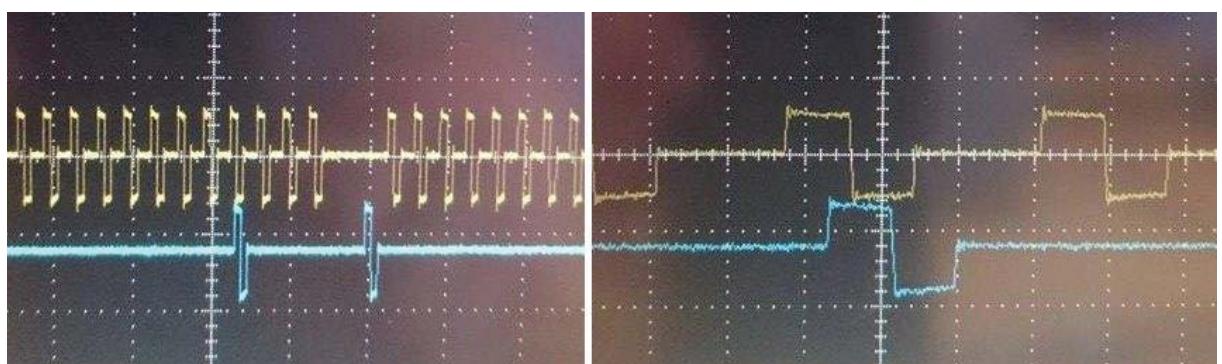

Figure 5.4.3: The cam- (blue) and crank (yellow) signals with a displacement of $\frac{1}{2}^\circ$.

Figure 5.4.4: The cam- (blue) and crank (yellow) signals with a displacement of 1° .

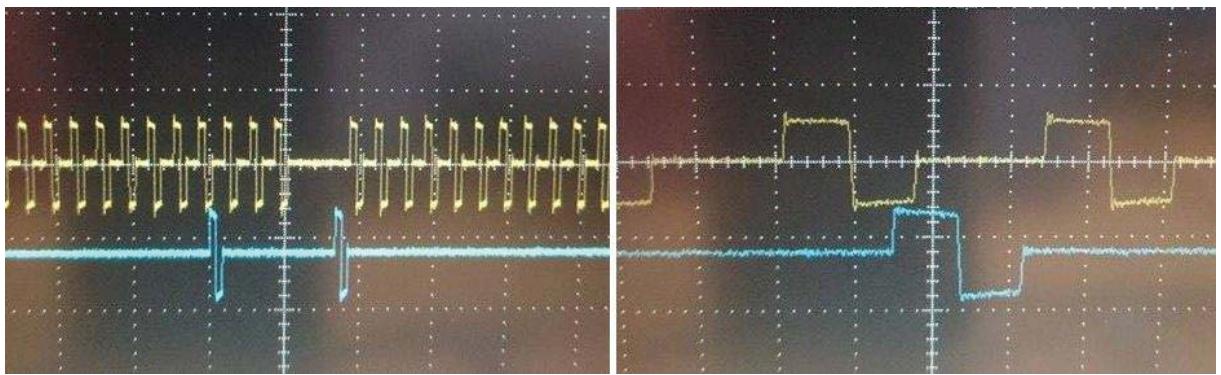

Figure 5.4.5: The cam- (blue) and crank (yellow) signals with a displacement of 2° .

6. Discussion and conclusion

The purpose of this thesis work was to design a Speed Sensor Simulator Box that can be used at tests and measurements of ECM's. After 10 weeks of work, the result is a functional product that meets the given specifications. We have succeeded to create a unit which contains software as well as electronic hardware that together generate and process cam and crank signals.

The problems that were formulated before the start of the thesis work have been managed to be covered in a good way. The signal generation is performed through Arduino™ and the selected components of the constructed circuit board are based on tests and measurements. To be able to determine the appropriate components by tests, Volvo has given us free choice of purchasing. This has given us a greater selection and facilitated the work.

Before the appropriate circuit was determined, different solutions were tested. As previously mentioned, the buffer was not a part of the original circuit. However, this was needed to provide an increased power to the transformer. Another test was to use a low-pass filter between the Arduino™ outputs and the operational amplifier, in order to get a sinusoidal signal. The low-pass filter worked as intended, but we quickly understood that this would not work all the time since the adjustment of RPM generates different frequencies. This would result in a filter not working at certain speeds. Our mentor at Volvo also explained that the importance is not to have a sinusoidal signal, but to have a signal with a quick zero-crossing between the maximum and minimum amplitude. Therefore, the filter could be neglected.

The software is based on the open-source program code called Ardu-Stim. Before the beginning of this project, none of us had any particular knowledge of Arduino™. The code needed to be carefully reviewed in order to be able to modify the necessary parts. This was facilitated by previous programming skills as well as all the information available online.

One thing that was quite tricky was to get a functional display. For some reason, the original pin configuration for the LCD did not work. After a bit of research we found out that one of the pins that was used by the LCD also were used by one of the Arduino™ timers. By initializing available pins for the LCD, this was solved.

The product itself is a clean box which is easy to use. Since the project had a time limit of 10 weeks, the product design could not be too advanced. However, it could have been done with some improvements. A bigger display or perhaps a touch screen is two examples. Another upgrade that can be developed in the future is the possibility of switching patterns with a potentiometer. This could possibly be achieved if more time were given.

Appendices

Appendix A – Schematic

Appendix B – Specification from Volvo

4.1.7 Engine speed (CAM – CRANK)

VR and Hall effect sensors should be possible to use for this purpose.

One CAM revolution requires two crank revolutions

Max engine speed: > 3600rpm
 Min engine speed: <10rpm
 Max resolution: 1rpm
 Crank tooth angle: 6° / tooth -> 60 possible teeth (some missing)
 Number of CAM teeth, Min: 5
 Max: 21

4.1.7.1 Synchronisation CAM - Crank

CAM Sync: +/- ¼ °Crank @ engine speed <1000rpm
 +/- ½ °Crank @ engine speed <1500rpm
 +/- 1 °Crank @ engine speed <3000rpm
 +/- 2 °Crank @ engine speed >3000rpm

The sync value should be given in 0.1° Crank and there should be a function in SW adapting to the above limitations.

Max engine speed [r/m]	Resolution [° Crank]	r/s	Number of degrees	Resolution Freq [Hz]	Number of "teeth"	Tooth Freq	Resolution Period Time [us]	Diff [ns]	Freq (MHz)
1000	0,5	16,67	360	12000	60	1000	83,3		
999	0,5	16,65	360	11988	60	999	83,4	83,4	11 988
1500	1	25,00	360	9000	60	1500	111,1		
1499	1	24,98	360	8994	60	1499	111,2	74,1	13 491
2100	2	35,00	360	6300	60	2100	158,7		
2099	2	34,98	360	6297	60	2099	158,8	75,6	13 224
3000	4	50,00	360	4500	60	3000	222,2		
2999	4	49,98	360	4498,5	60	2999	222,3	74,1	13 496
3500	5	58,33	360	4200	60	3500	238,1		
3499	5	58,32	360	4198,8	60	3499	238,2	68,0	14 696

010203

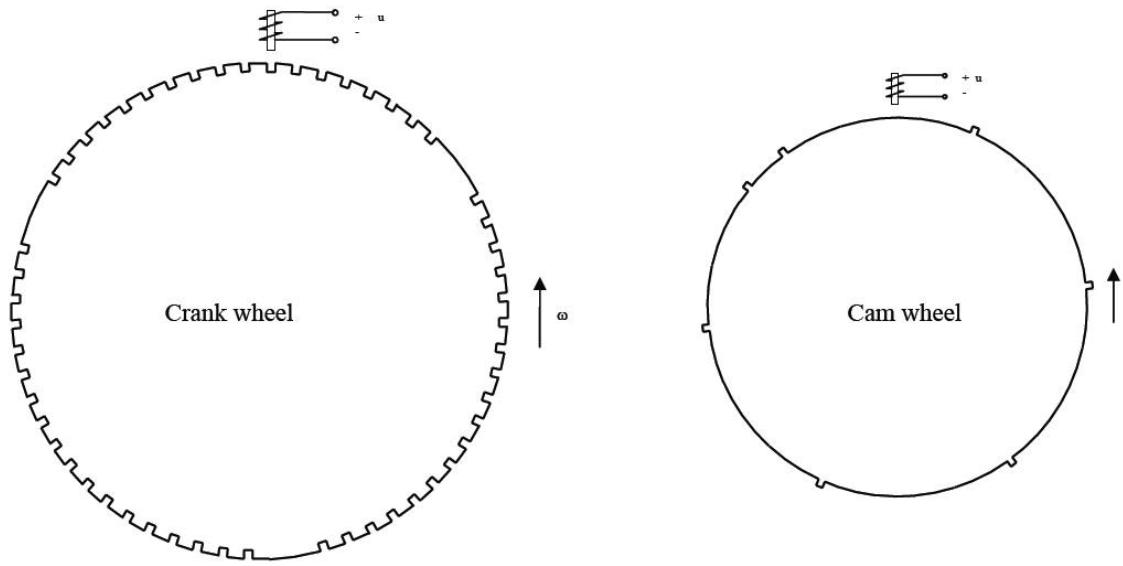

Subject

Cam and Crank Signals

(Receiver)

3.10.1 Cam and crank wheel in position of TDC cylinder 1

Firing order: 1, 5, 3, 6, 2, 4

Appendix D – Modified Ardu-Stim program code

Appendix D.1 – ardustim.ino
